TRALI has been associated with both neutrophil and HLA antibodies. Antibodies reported in these reactions include HNA-1a, HNA-1b, HNA-2, HNA-3a, and HLA class I and II antibodies. Most of these cases involve the passive transfusion of the offending antibody in donor plasma, as contrasted with the reactivity of the recipient's antibody with donor leukocytes to cause febrile nonhemolytic reactions. Retrospective studies involving antibodies to HNA-3a have implicated blood components from single donors with anti-HNA-3a in several TRALI cases.[257]

NEUTROPHIL ANTIGENS SUMMARY

Five neutrophil antigen systems, HNA-1,HNA-2, HNA-3, HNA-4 and HNA-5, have been well described. HNA-1 antigens are located on FcγRIIIb, and antibodies to these antigens are frequently implicated in autoimmune and alloimmune neutropenia. HNA-2 is located on CD177 glycoprotein, and antibodies to HNA-2 are found in patients with alloimmune and autoimmune neutropenia. Antibodies to HNA-3a are rare, but, relative to other neutrophil antibodies, may be more frequently associated with cases of TRALI. The significance, if any, of HNA-4a and HNA-5a antibodies is uncertain.

CHAPTER 115

PRINCIPLES OF PLASMA AND PLASMA DERIVATIVES

Alexandra Jimenez, Christopher D. Hillyer, and Beth H. Shaz

Plasma and its derivatives are well-established clinical resources, but cost, risk of infectious disease transmission, although rare, and other adverse effects mandate their appropriate use. Even to this day, however, much still remains to be clarified regarding the appropriate clinical indications/protocols for plasma product use. Plasma can be separated from red blood cells (RBCs) through centrifugation of whole blood at the time of collection or can be collected by apheresis as a single product or as a by-product of platelet or RBC apheresis. Plasma can be processed into derivatives through cold ethanol fractionation (method of Cohn),[1] additional factor purification steps, and pathogen inactivation.[2] With the advent of genetic and cellular engineering technologies, the development of recombinant products with no human proteins is possible. In this chapter, the features and uses of plasma products, which include fresh frozen plasma (FFP), plasma frozen within 24 hours of phlebotomy (FP24), thawed plasma, liquid plasma, solvent detergent treated plasma (SD-plasma), pathogen-reduced plasma, cryoprecipitate, cryoprecipitate-reduced plasma (CRP), as well as plasma derivatives, including albumin, intravenous and intramuscular immunoglobulin, and purified and recombinant coagulation factor concentrates are discussed.

PLASMA

Plasma is the acellular, fluid compartment of blood and consists of 90% water, 7% protein and colloids, and 2% to 3% nutrients, crystalloids, hormones, and vitamins. The protein fraction contains the soluble clotting factors: fibrinogen, factor XIII, von Willebrand factor (vWF), factor VIII primarily bound to its carrier protein vWF, and the vitamin K-dependent coagulation factors II, VII, IX, and X. Primary indications for transfusion of plasma are either general clotting factor replacement or specific factor replacement when purified or recombinant products are not available.[3] Clotting proteins are the constituents for which transfusion of plasma is required. Plasma products include FFP, FP24, thawed plasma, SD-plasma, and pathogen-reduced plasma,[4] which are clinically equivalent.

Products

FFP and FP24

Plasma frozen at −18°C or colder within 8 hours of donation (or within 6 hours with the use of some storage bags after apheresis collection) can be labelled as FFP. A second type of frozen plasma, the most commonly used in the United States, is FP24 plasma. FP24 is frozen at −18°C or colder within 24 hours of collection. FFP and FP24 may be stored up to 1 year before use, at which time it is thawed at 37°C for 20 to 30 minutes. After thawing, plasma is stored at 1°C to 6°C and transfused within 24 hours, after which it becomes thawed plasma (described below). A direct comparison between FFP and FP24 mean factor activity immediately post-thaw indicates that either product can be used interchangeably such that they are considered clinically equivalent (Table 115.1).[5]

Thawed Plasma

Thawed FFP and FP24 stored at 1°C to 6°C for up to 5 days is termed thawed plasma and most coagulation factors remain relatively stable in it. Although there is evidence that activity levels for factors V, VII, and VIII decrease, this is not considered to be of clinical significance, as the mean factor activity levels for 5-day-old thawed plasma remain above the minimum activity required for surgical hemostasis (see Table 115.1).[6] Compared to frozen plasma, stored thawed plasma improves patient care as there is no preparation time required resulting in a decreased turnaround time, and because of longer shelf life, it reduces wastage rate.[7]

Cryoprecipitate-Reduced Plasma

CRP, also known as cryosupernatant or cryoreduced plasma, is the remaining supernatant after the removal of cryoprecipitate from FFP, which is subsequently refrozen. This product has significantly decreased levels of factor VIII, factor XIII, vWF, fibrinogen, and fibronectin. The primary indication of CRP is for transfusion or plasma exchange in patients with thrombotic thrombocytopenic purpura (TTP).[8] It can be thawed and stored for up to 5 days at 1°C to 6°C and is termed thawed plasma cryoprecipitate reduced.

Liquid Plasma

Liquid plasma is plasma that is separated from whole blood at any time during storage and up to 5 days after the whole blood expiration date. Liquid plasma is never frozen and is maintained at 1°C to 6°C and stored for 26 days or 40 days depending on the anticoagulant preservative used to collect the whole blood. Clotting factor levels progressively decrease over time, particularly labile clotting factors (i.e., factors V and VIII).[9] This product contains viable leukocytes, and thus would need product modifications (leukoreduction or irradiation) prior to transfusion in at-risk individuals (e.g., immunocompromised). It is used primarily for immediate treatment of patients undergoing massive transfusion due to massive hemorrhage.[10]

Lyophilized Plasma Also Known as Freeze-Dried Plasma

Lyophilized plasma is produced and pooled from 10 or fewer apheresis plasma donors. The plasma undergoes a cryodesiccation process to form a 215 g powder in a sterile bottle. The plasma is then rehydrated for use via 200 mL of sterile water with soft agitation. While not in use yet in the United States (but used in Europe and in the US military), clinical trials in the US are underway. Studies suggest that the product is safe and efficacious for treatment of traumatic hemorrhage.[11]

Solvent-Detergent Plasma

SD-plasma is US Food and Drug Administration (FDA)-approved (Octaplas, Octapharma USA Inc., Hoboken, NJ, USA; marketed as Octaplas LG in Europe and other markets) and is manufactured from ≤2500 pooled plasma products that have been treated with solvent (tributyl phosphate)/detergent (triton X-100) to inactivate lipid-enveloped viruses (HIV, hepatitis B, hepatitis C).[12,13] Additionally, the product is tested for hepatitis A and parvovirus B19. The product

TABLE 115.1 Average Coagulation Factor Activity in FFP and FP24 at the Time of Thaw and in Thawed Plasma After 5 Days of Storage at 1°C to 6°C

Factor	FFP	FP24	Thawed Plasma at Day 5	~Minimum Activity Required for Surgical Hemostasis
I (mg/dL)	280	309	303	100
II (IU/dL)	97	97	96	20–40
V (U/dL)	85	86	59	25
VII (IU/dL)	105	89	77	10–20
VIII (IU/dL)	81	66	48	30
IX (IU/dL)	82	88	84	25–30
X (IU/dL)	94	94	91	10–20

FFP, Fresh frozen plasma; *FP24*, 24 hours after phlebotomy.

is distributed in 200 mL containers, frozen at −18°C with a shelf life of 1 year. This pooled and treated plasma product has a lower rate of allergic reactions and has a substantially reduced risk of transfusion-related acute lung injury (TRALI), as the manufacturing process is considered to dilute neutrophil antibodies and soluble human leukocyte antigens (HLAs).[14]

Pathogen-Reduced Plasma

Other pathogen-reduction methods have been developed, including amotosalen photochemical treatment with ultraviolet (UVA) light (INTERCEPT plasma, Cerus Corp, Concord, CA), which is FDA approved. Riboflavin-treated plasma with UVA light (Mirasol Pathogen Reduction Technology, Terumo BCT, Denver, CO) and methylene blue-treated plasma (Theraflex System, MacoPharma, Mouvaux, France) are used outside of the United States, but these have not yet been FDA approved. Studies in Europe show that these methods are also quite effective at reducing the risk of pathogen contamination.[15]

Recovered and Source Plasma (Plasma for Manufacturing)

There are plasma products that are not used for transfusion but are used for further manufacturing into plasma derivatives. These products include recovered plasma that are derived from whole blood and are sent to a manufacturer from a collection facility through a "short supply agreement." Source plasma, an FDA licensed product, is collected by apheresis which is intended for further manufacturing. The Plasma Protein Therapeutics Association promotes safe collection and manufacturing practices of plasma derivatives. Source plasma can be collected more frequently under special donor programs; the donors can be compensated for their time.[15]

Convalescent Plasma

Convalescent plasma is plasma obtained from a patient who has recovered from or has been vaccinated against an infectious disease and has high titers of neutralizing antibodies (e.g., COVID-19). Convalescent plasma is transfused to infected patients to prevent or treat severe or life-threatening complications. COVID convalescent plasma potentially is beneficial if transfused early in the disease course or to patients who are immunocompromised.[16] Convalescent plasma can also be pooled and treated, as described below, to create a hyperimmune globulin.

Indications

Most guidelines consistently support plasma transfusions for the treatment of bleeding in patients with multiple acquired coagulation factor deficiencies, as seen in liver failure, disseminated intravascular coagulopathy (DIC), massive transfusion, and in certain indications as a factor replacement during therapeutic plasma exchange (TPE; Table 115.2).[17,18] However, the optimal transfusion strategy for these indications is not well established. Currently, there are no evidence-based laboratory value "triggers" for plasma administration, and any recommendation needs to be carefully weighed against the patient's presence, or risk, of bleeding.[9] Plasma transfusion is not indicated for use in clotting disorders where purified, concentrated, or recombinant clotting factors are available (e.g., factor VIII and IX deficiencies).

Plasma is typically indicated when prothrombin time (PT) and/or partial thromboplastin time (PTT) are greater than 1.5 to 1.7 times normal paired with the presence of bleeding or anticipated bleeding. These current recommendations are justified as there is compelling evidence that plasma transfusions are ineffective in correcting mild to moderate abnormalities of coagulation screening tests.[20] However, marked reductions in substantially elevated coagulation studies can occur with relatively modest plasma transfusion volumes. This response to plasma can be largely explained because of the nonlinear, exponential relationship between clotting factor activity levels and coagulation test results (Fig. 115.1).[21]

Audits of recent transfusion practices have consistently demonstrated that plasma product use is inappropriately high. Recent estimates suggest up to 83% (reported range: 10% to 83%) of plasma transfusions are not administered according to published guidelines.[22] The most commonly cited reason for plasma administration is a preprocedural elevation in coagulation studies.[22] This indication is not evidence-based, especially when the coagulation abnormality is mild-moderate.[24] Moreover, plasma should not be used as a volume expander or as a source of nutrients. Clinical situations where plasma transfusions may be beneficial are described below.

Liver Failure

Patients with liver failure may develop low levels of the vitamin K-dependent clotting factors (factors II, VII, IX, and X). These patients develop a prolonged PT/INR, PTT, and thrombin time.

TABLE 115.2 Indications for Plasma Product Transfusion

Indicated
Disseminated intravascular coagulation and bleeding or high risk of bleeding
Liver failure
Massive transfusion
Multiple acquired coagulation factor deficiency
Plasma infusion or exchange for thrombotic thrombocytopenic purpura and other thrombotic microangiopathies, diffuse alveolar hemorrhage, and catastrophic antiphospholipid syndrome
Rapid reversal of warfarin effect when prothrombin complex concentrate is not available
Replacement of an inherited single plasma factor deficiency for which no coagulation factor concentrate exists
Not Indicated
Burns
Immunodeficiency
Source of nutrients
Volume expansion
Wound healing

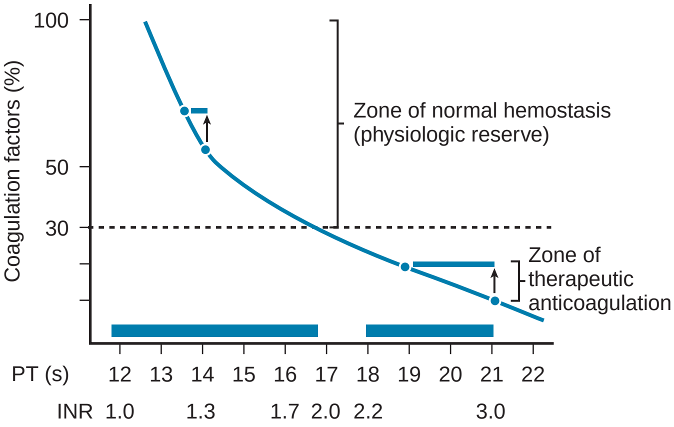

Figure 115.1 RELATIONSHIP BETWEEN FACTOR ACTIVITY LEVELS AND COAGULATION STUDIES. The general relationship between the concentration of coagulation factors and the result of PT and INR studies. The normalization of modest elevations in the INR required much larger volumes of plasma than would be expected and modest doses of plasma can result in marked changes in the INR when markedly elevated. The cause of this phenomenon can be explained by the nonlinear, exponential relationship between coagulation factor concentration and standard coagulation test results. Small increases of coagulation factors correlate with marked changes in coagulation studies when coagulation factors are depleted. The opposite is true when the coagulation factors are at higher concentrations. *INR*, International normalized ratio; *PT*, prothrombin time. *(Adapted from Kor DJ, Stubbs JR, Gajic O. Perioperative coagulation management: fresh frozen plasma. Best Pract Res Clin Anaesthesiol. 2010;24[1]:51–64.)*

Fibrin split products may also be elevated in these patients, and in later stages, the fibrinogen level may be decreased. Hemorrhage, most often secondary to an anatomic lesion, may be worsened by the coagulopathy. Patients undergoing orthotopic liver transplantation complicated by preexisting severe liver disease and liver disease with DIC are two examples that may require large plasma transfusion volumes.[25,26]

While elevations in coagulation tests are correlated with the incidence of bleeding in these patients, growing evidence now suggests that the PT and PTT are, in themselves, poor predictors of surgical bleeding.[27] The reason for this lack of association may be twofold. First, PT and PTT values do not correlate well with plasma factor activity levels. One study identified that up to 50% of patients with abnormal coagulation tests had coagulation activity levels considered sufficient for adequate thrombus formation. Moreover, studies demonstrate that mild abnormalities in these coagulation tests do not correct—even with infusion of large quantities of plasma—because of the mathematical difficulty of infusing normal levels of factors into mildly deficient blood to get enough plasma to decrease the PT/PTT (see Fig. 115.1).[28] Second, the lack of increased/excessive bleeding noted in some patients with liver disease and elevated coagulation tests may be caused by a parallel reduction in anticoagulant proteins, such as proteins C and S.[29,30] Therefore, patients with liver disease may not bleed as much as expected because they retain a homeostatic balance between coagulant and anticoagulant proteins. Evidence suggests that the use of plasma in the context of severe liver disease and perioperatively during liver transplant does not significantly improve outcome.[31] As a result, the use of plasma should be more limited in liver disease and hepatectomy patients. Plasma transfusion in these patients should be guided by a combination of clinical assessment, evidence and degree of bleeding, and coagulation test results. Plasma products are currently not recommended prophylactically before a surgical challenge or liver biopsy in these patients. However, as noted previously, plasma transfusions may be considered when the PT/PTT is greater than 1.5 to 1.7 times normal, or if the INR is 2.0 or greater when the risk of bleeding is considered high.

Massive Transfusion

Massive transfusion is generally defined as receiving 10 or more units of RBCs within 24 hours (or one blood volume). Trauma patients may arrive at the hospital with a prolonged PT (termed acute trauma-induced coagulopathy) due to protein C activation, fibrinogen depletion, and platelet dysfunction. Acute trauma-induced coagulopathy is associated with increased mortality and increased use of blood products.[32] Trauma patients can also develop a secondary coagulopathy, termed the lethal triad—dilutional coagulopathy, acidosis, and hypothermia.[33] The dilutional coagulopathy is secondary to the administration of crystalloid and RBCs without coagulation factor support.[34,35] Guidelines supported by randomized control trials recommend early use of tranexamic acid, an antifibrinolytic.[36]

Studies have shown that the early use of plasma and platelets in trauma patients undergoing massive transfusion appears to decrease the incidence of secondary coagulopathy (lethal triad) and improve survival in these patients. The Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study[37] demonstrated that early transfusion of plasma (within minutes of arrival to a trauma center) was associated with improved 6-hour survival after admission. The Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial[38] compared the effectiveness and safety of a 1:1:1 (plasma:platelet:RBC) transfusion ratio with a 1:1:2 transfusion ratio in trauma patients who were predicted to receive a massive transfusion. This randomized clinical trial found no overall difference in survival based on transfusion ratio, but did find that those who were randomized to receive more plasma (1:1:1 ratio) achieved hemostasis more quickly and frequently.

Questions regarding best practice remain.[39] Currently, the use of cold stored whole blood is being evaluated and used in the prehospital and early hospital acute bleeding episodes. Studies support the use of whole blood early in trauma care prior to the need of specific blood components as a result of laboratory testing.[40] Other studies are investigating the early use of cryoprecipitate or fibrinogen concentrates as part of massive transfusion protocols.[41] Recently trials investigating the benefits of hospital plasma transfusion have been published. Prehospital plasma transfusion may benefit trauma victims who have longer transit time and suffered blunt trauma.

To improve the speed of identifying and treating coagulation abnormalities, some protocols incorporate thromboelastography (TEG) or other point-of-care tests.[44] TEG technology provides a dynamic and global assessment of the coagulation process and can provide rapid assessments of the patient's platelet function, coagulation cascade, and fibrinolysis, aiding in determining what medications or blood products the patient needs.[45]

Massive transfusion in other conditions, such as liver, cardiac, or orthopedic surgery and obstetric hemorrhage, likely have a different pathophysiology and thus transfusion management of these patients may be different than trauma patients.[46] Institutions should have policies in place for rapid availability of blood products and laboratory testing in these patient populations.

Disseminated Intravascular Coagulation

DIC may be secondary to sepsis, liver disease, hypotension, hypoperfusion, trauma, obstetric complications, leukemia (usually promyelocytic), or underlying malignancy. Successful treatment of the underlying cause is paramount. Recent guidelines suggest that plasma therapy should not be initiated based on abnormal laboratory results alone.[47] Rather, patients with DIC and bleeding, those requiring an invasive procedure, and those at risk for bleeding complications should be given plasma in amounts sufficient to correct or ameliorate the coagulopathy or hemorrhagic diathesis. Large volumes of plasma are often necessary to correct the coagulation defect in these patients (up to 30 mL/kg).[48] However, in patients with severe liver disease, bleeding, and DIC, plasma infusions often fail to normalize the PT and PTT.[49]

Rapid Reversal of Warfarin Effect

Warfarin inhibits the hepatic synthesis of vitamin K-dependent clotting factors (factors II, VII, IX, and X) by blocking the recovery of the form of vitamin K that is active in the carboxylation of these proteins. Warfarin therapy induces functional deficiencies of these factors, which correct within 48 hours after the discontinuation of warfarin if diet and vitamin K absorption are normal.

The use of plasma in the context of warfarin anticoagulation is well established but is no longer the preferred treatment. If available, four factor prothrombin complex concentrate (PCC) should be chosen as the first-line therapy for rapid reversal of life- or limb-threatening warfarin anticoagulation. In patients anticoagulated with warfarin who have active bleeding, require emergency surgery, or have serious trauma, the deficient clotting factors can be immediately provided by PCC. PCC can reverse a warfarin-induced coagulopathy faster with lower mortality and less volume overload than plasma or vitamin K alone.[50] Neither PCC nor plasma is indicated for warfarin reversal when the patient is not bleeding and has an INR less than 9, as vitamin K administration corrects the coagulopathy in 12 to 18 hours. INR levels need to be closely followed to ensure warfarin reversal is sustained. Plasma transfusion is only indicated for rapid reversal when no PCC is available.

Thrombotic Thrombocytopenic Purpura and Other Thrombotic Microangiopathies

In patients with TTP, TPE with plasma as the replacement fluid is lifesaving. Plasma infusion or exchange is also critical in the treatment of individuals who have congenital TTP. TPE has decreased the mortality of TTP from over 90% to less than 10% (see Chapter 132).[51] Six randomized control trials have demonstrated that TPE is most effective in patients who have an autoantibody to ADAMTS13 (ADAM metallopeptidase with thrombospondin type 1 motif 13).[52,53] This is caused by both the removal of a patient's plasma containing the inhibitor coupled with the addition of donor plasma containing the functional vWF-cleaving protease.[54] The FDA has also approved the use of CRP for TTP. Some authorities advocate CPR use as a first-line therapy for TTP, as these products have a lower level of vWF than FFP, comparable ADAMTS13 activity, and lower amounts of ADAMTS13–larger vWF multimer complexes. However, the most recent multicenter prospective randomized trial comparing TPE with plasma and CRP for the initial treatment of TTP demonstrated the two products were equivalent.[55]

The treatment of TTP has changed with the approval of caplacizumab, which inhibits the interaction between vWF multimers and platelets. Caplacizumab treatment is associated with faster platelet count recovery, lower incidence of TTP-related death or thromboembolism, and TTP recurrence.[56]

TPE is not indicated in the treatment of individuals with diarrhea-associated hemolytic uremic syndrome (HUS) (also termed thrombotic microangiopathy, Shiga toxin mediated) unless there are severe neurological symptoms. Seven randomized control trials evaluated the efficacy of TPE for typical cases of HUS. These trials found that the plasma use was not superior to supportive therapies alone.[53] TPE with plasma replacement fluid, however, is currently indicated in diarrhea-negative (atypical) HUS (aHUS), which is caused by several inherited and sporadic conditions that lead to the uncontrolled activation of the alternative complement system (i.e., deficiency or autoantibody to complement factor H). Typically, all patients diagnosed with aHUS are empirically treated with TPE or plasma transfusions until underlying disease or mutation is further defined, which then determines treatment.[57] TPE has been theoretically proposed to effectively remove the potentially causative autoantibody or mutated circulating complement regulator, while replacing absent or defective complement regulators. However, the clinical response varies depending on the underlying cause (see Chapter 132).

TPE with plasma replacement may also be indicated in other thrombotic microangiopathies including those due to medications, most notably ticlopidine and clopidogrel, and potentially cyclosporine or tacrolimus. Another example is in the treatment of thrombotic microangiopathy associated with stem cell transplantation.[51]

Plasma as replacement fluid, either partially or completely, for TPE is used in other diseases with risk of hemorrhage caused by the resulting coagulopathy, such as diffuse alveolar hemorrhage, liver failure, and perioperatively (see Chapter 116).

Prophylactic Use

Studies have shown that prophylactic administration of plasma to non-bleeding recipients with abnormal coagulation studies (i.e., PT, PTT, INR) is unlikely to produce a clinical benefit and unnecessarily exposes the patient to the risks of plasma transfusion. Moreover, systematic reviews of the predictive value of a prolonged PT or PTT found no significant difference in the risk of bleeding between patients with a prolonged PT or PTT and those with normal clotting parameters in the settings of bronchoscopy, central vein cannulation, angiography, liver biopsy, or lumbar puncture.[58] This is supported by randomized control trials and meta-analyses which have evaluated the efficacy of the prophylactic use of plasma products to reduce the risk of bleeding.[59,60] One trial, the Northern Neonatal Nursing Initiative Group Trial, randomized 776 neonates and evaluated whether plasma transfusion prophylaxis could prevent intraventricular hemorrhage in comparison with volume expanders (gelofusine or dextrose-saline).[61] In a second large randomized clinical trial, 275 patients were randomized to see whether plasma transfusions could prophylactically prevent bleeding in acute pancreatitis patients.[62] Neither large study showed clinical benefit of prophylactic plasma use. In one systematic review, 55 other randomized clinical trials were reviewed and evaluated. Only 17 of these 55 involved a control group that did not receive plasma.[63] Overall, like the two largest studies, the results of these randomized control trials failed to show evidence for the efficacy of prophylactic plasma use across multiple clinical and laboratory outcomes. Similarly, a second meta-analysis evaluated 25 independent studies of minor surgical procedures and found that there was no significant difference in bleeding risk between those who did and did not have a coagulopathy.[64] Despite this evidence, current recommendations still indicate that a pretransfusion INR of ≥ 1.5 to 1.7 be used as a transfusion trigger, as the prophylactic use of plasma is theoretically justified when the clinical risk of bleeding is greater than potential harms of using plasma.

Dosage

One unit of plasma derived from a unit of whole blood is 200 to 280 mL. When plasma is collected by apheresis, as much as 800 mL can be obtained from one individual ("jumbo" plasma units), but these are then divided into volume of 200 to 250 mL. On average, there is 0.7 to 1 unit/mL of activity of each coagulation factor per milliliter of plasma and 1 to 2 mg/mL of fibrinogen. The appropriate dose of plasma may be estimated from the plasma volume, the desired increment of factor activity, and the expected half-life of the factor being replaced (i.e., factor VII has a half-life of only 4 to 6 hours, and thus plasma doses should be repeated every few hours if replacing factor VII in a patient with factor VII deficiency). Alternatively, the plasma dosage may be estimated as 10 to 15 mL/kg, and with that dose all clotting factor activities will increase by ~30% in the absence of rapid ongoing consumption[65] Ideally, plasma should be ordered as the number of milliliters to be infused. The frequency of administration depends on the clinical response to the infusion and correction of laboratory parameters. Moreover, plasma infusions should be given as close to the time as it is needed to allow for its maximum hemostatic effect if given pre-procedure. Complete normalization of coagulation laboratory values will likely not be achieved with plasma infusion, and minimal elevations of PT/INR (e.g., INR <1.5) are usually not corrected with plasma administration.[66]

Compatibility

Plasma is screened for unexpected RBC antibodies during product testing and should be ABO-type compatible with the patient (see below).[18] However, following traumatic injury, the patient's blood type is often unknown. Emergency release plasma, traditionally group AB, is used until blood typing has been completed, and the plasma used can be switched to the patient's identified ABO type. The advantage in using group AB plasma is its lack of anti-A and anti-B antibodies, thus avoiding the risk of acute hemolytic transfusion reactions. However, only 4% of the population is group AB. In order to increase the availability of plasma for emergency use during massive transfusion, group A plasma, with or without assuring low titers of anti-B, is now being used.[67] Studies demonstrate no increased risk to the recipient and no adverse effect on clinical outcomes.[68] Since patients typically receive group O RBCs and about 80% of the population is group O or group A, the risk of hemolysis is low.

	Plasma Product ABO Type			
Patient ABO type	**O**	**A**	**B**	**AB**
O	Yes	Yes	Yes	Yes
A	No	Yes	No	Yes
B	No	No	Yes	Yes
AB	No	No	No	Yes

Yes = compatible blood types.
No = incompatible blood types.
Plasma units do not need to be matched for RhD, as the number of RBCs is negligible. Additionally, frozen plasma does not need to be leukoreduced or irradiated.

Adverse Events

Plasma transfusions, like all blood products, have the potential for infectious and noninfectious adverse events. Transfusion transmitted diseases, although rare, traditionally include HIV, hepatitis B, and hepatitis C (see Chapter 118). Noninfectious risks include allergic reactions, TRALI, transfusion-associated circulatory overload (TACO), and hemolytic reactions (see Chapter 117).[69]

CRYOPRECIPITATE

Cryoprecipitate is prepared from 1 unit of FFP thawed at 1°C to 6°C. The precipitate is then refrozen and stored at −18°C or colder for 1 year. Cryoprecipitate, volume of 10 to 15 mL, contains 80 to 100 units of factor VIII, 150 to 250 mg of fibrinogen, and 50 to 60 mg of fibronectin as well as vWF and factor XIII. Pathogen-reduced cryoprecipitated fibrinogen complex is now approved for use in acquired fibrinogen deficiency or for replacement of factor XIII or von Willebrand factor, but not for FVIII replacement, if no specific factor concentrates are available.

Cryoprecipitate takes 10 to 15 minutes to thaw at ~37°C, and then requires pooling before infusion. Prepooled (pooled before storage) cryoprecipitate products are available, easing the burden of preparation on the transfusion services. Once pooled and thawed, cryoprecipitate is maintained at 20°C to 24°C and outdates in 4 hours (6 hours if unpooled or pooled in a closed system).

Indications

Cryoprecipitate is used predominantly to treat bleeding associated with fibrinogen deficiency and in the manufacturing of fibrin sealants and glue (Table 115.3). Cryoprecipitate should not be used to treat factor XIII, vWF, and factor VIII deficiencies, as virally inactivated factor concentrates are available. Human fibrinogen concentrate is also available, and FDA approved, and is primarily used for congenital fibrinogen factor deficiency in the United States and broader indications in Europe.

Like plasma, recent studies also indicate that cryoprecipitate is not used appropriately in clinical practice. One large audit, for instance, demonstrated that across 25 Canadian hospitals and 4370 units of cryoprecipitate transfusion, only 24% of transfusions were considered clinically appropriate, and 34% of cryoprecipitate transfusions were deemed inappropriate according to published national guidelines (i.e., Transfusion Medicine Advisory Group of British Columbia, Canada Guidelines for cryoprecipitate transfusion).[70]

TABLE 115.3 Administration of Cryoprecipitate

Indicated
Congenital afibrinogenemia if fibrinogen concentrate unavailable
Dysfibrinogenemia if fibrinogen concentrate unavailable
Factor XIII deficiency if factor XIII concentrate unavailable
Fibrinogen deficiency if fibrinogen concentrate unavailable
Massive transfusion
Reversal of thrombolytic therapy
Possibly Indicated
Amniotic fluid embolism (used as last resort to replace depleted fibronectin)
Snake bites
Uremic bleeding

Fibrinogen Deficiency

Fibrinogen deficiency is the primary indication for cryoprecipitate transfusion. The deficiency may be caused by congenital afibrinogenemia or dysfibrinogenemia, severe liver disease, DIC, or massive transfusion.[48,71,72] Patients with the latter indications often have concomitant decreases in clotting factor levels and require the coadministration of plasma products. It is important to obtain fibrinogen measurements because levels less than 100 mg/dL cause prolongation of the PT and PTT, despite adequate clotting factor replacement. Very low levels of fibrinogen occur during liver transplantation (<100 mg/dL), where transfusion support with cryoprecipitate is vital.[17,28]

A specific purified human fibrinogen concentrate is an alternative for direct fibrinogen replacement in isolated fibrinogen deficiencies, such as inherited hypofibrinogenemia. Fibrinogen concentrates undergo viral inactivation and have a standardized fibrinogen content; these are used preferentially over cryoprecipitate in some countries, but studies have not demonstrated a clinical benefit over cryoprecipitate.[73–75]

Fibrin Glue/Sealant

Fibrin glue/sealant results from the mixture of a fibrinogen source (from plasma, platelet-rich plasma, or allogeneic/autologous cryoprecipitate) with a thrombin source (bovine, human, or recombinant). The enhanced local hemostasis achieved by the sealant product is through the action of thrombin on fibrinogen. "Fibrin glue" is a non–FDA-approved thrombin/preparation, and it has been widely used in Europe for many years. Fibrin sealants are FDA-approved alternatives to fibrin glue and are advantageous over locally made fibrin glues, because of standard dosing.[76] Fibrin glues/sealants can be used for multiple surgical purposes, including as a topical hemostat (creating a blood clot to halt bleeding), as a sealant (agents to prevent leakage of potentially nonclotting fluids [i.e., cerebrospinal fluid]), or as an adhesive (bonds different tissues together).

The safety profile of each product differs depending on the product components and source. Bovine thrombin has been reported to cause anaphylaxis (because of bovine allergies), coagulopathy through formation of antibodies to factor V or II, and rarely death caused by severe systemic hypotensive reactions.[77] Consequently, bovine products have an FDA mandated black-box warning on their package inserts. Pooled human plasma sources have the potential risk of viral or prion disease transmission. Reports indicate that hepatitis A and parvovirus B19 are particularly difficult to remove from these products despite current cleansing and filtration methods, and it is recommended that patients be counseled about this risk, although, given the current safety of the blood supply, the infectious risks are extremely low. Recombinant products, while eliminating the risk of infectious transmission or antibody formation, may also cause allergic reactions because of the hamster or snake proteins used to manufacture the product. Lastly, autologous fibrin glue preparations have been used, although the infectious risks (e.g., HIV and hepatitis) associated with the use of heterologous fibrin glue are eliminated by replacement with the autologous source, but are resource intensive.

Alternatively, albumin mixed with glutaraldehyde has been used to form both an effective sealant and adhesive.[78] The FDA has currently approved an albumin-based product to seal large blood vessel anastomoses and to reattach layers of the aorta in the context of an aortic dissection. Other successful reported uses include as a sealant in breast cancer surgery, and to reduce air leaks in lung volume reduction procedures. Side effects of this compound can be significant, however, and include nerve and muscle necrosis, sinoatrial node damage, calcium metabolism abnormalities, mucosal and skin irritation, adhesive emboli, limitation of aortic growth, and pseudoaneurysms.

Massive Transfusion

While most studies regarding massive transfusion evaluate the use of platelets and plasma, some studies suggest that regular doses of cryoprecipitate may also help improve survival. In general, the current use of cryoprecipitate in massive support is not standardized and the use is based on theoretic efficacy. According to the recently published PROMMTT study, there are wide differences (7% to 82%) in the use of cryoprecipitate at US level 1 trauma centers, and inclusion of cryoprecipitate in massive transfusion protocols vary significantly. Specifically, some PROMMTT sites used cryoprecipitate after a certain number of RBC units infused, while others used fibrinogen level triggers, such as 100 mg/dL.[76] While the PROMMTT study found no significant differences in mortality between those that did and did not receive cryoprecipitate, other studies have shown benefit. One study found that a high transfusion ratio involving cryoprecipitate in 214 massive transfusion patients resulted in improved 30-day survival (66% vs. 41%).[80] Another key study found that maintaining a ≥0.2 g fibrinogen/RBC (10 units of cryoprecipitate used for every 10 units of RBCs) unit ratio resulted in significantly higher survival rates (76% vs. 48%).[81] Lastly, military trauma patients in the MATTERs II study who received a combination of cryoprecipitate and tranexamic acid had the lowest observed mortality despite high injury severity scores (odds ratio, 0.34).[82] Consequently, while still under investigation, current data tentatively support the use of cryoprecipitate in the context of massive transfusion protocols, however cryoprecipitate remains indicated in the treatment of hypofibrinogenemia.[83] Outside of the United States and in clinical trials, fibrinogen concentrate is being used instead of cryoprecipitate in the treatment of massive hemorrhage.[84] See box on Severe Maternal Hemorrhage.

Uremic Bleeding

Abnormal bleeding is a common complication of uremia and is primarily caused by platelet dysfunction and defective interaction with endothelium. Use of cryoprecipitate as a source of vWF has been speculated to correct the platelet dysfunction. However, cryoprecipitate has been shown not to affect platelet aggregation in vitro, but it has been reported to shorten the bleeding time in some uremic patients.[90,91] Therefore, in addition to desmopressin, dialysis, erythropoietin, RBC transfusion, and conjugated estrogens, cryoprecipitate may have an adjunctive role.

SEVERE MATERNAL HEMORRHAGE

Major obstetric hemorrhage is a leading cause of maternal morbidity and mortality and is preventable and/or treatable. Significant obstetric hemorrhage is defined as active bleeding greater than 1000 mL within the 24 h following birth that continues despite the use of initial measures including first-line uterotonic agents and uterine massage. Early assessment and aggressive treatment of postpartum hemorrhage (PPH) are important for reducing morbidity and mortality rates. A critical first step in managing PPH is rapid recognition that clinically significant bleeding has occurred, with effective communication of the situation to the appropriate team members, both clinical and laboratory staff. Subsequent measures include immediate resuscitation with definitive action to arrest the bleeding (obstetric, surgical, and/or hematologic) and ongoing assessment and monitoring of the response to treatment. In these cases, blood ordering protocols specific to obstetric patients may be helpful. A massive transfusion protocol, like that seen in acute trauma patients, ensures sustained availability of blood products while the bleeding remains uncontrolled. Unique to maternal hemorrhage, hypofibrinogenemia is an important predictor for the later development of severe bleeding.[85] Consequently, point-of-care technologies, such as thromboelastography and rotational thromboelastometry, in addition to fibrinogen levels, can identify decreased fibrin clot quality during PPH, which correlate with low fibrinogen levels and can assist in transfusion management.[86,87] Early administration of 1–2 g tranexamic acid is also recommended, followed by an additional dose in cases of ongoing bleeding.[88,89] Early fibrinogen replacement using an appropriate dose of cryoprecipitate or fibrinogen concentrate may also be beneficial in these cases.

Dosage

The dosage of cryoprecipitate is calculated based on the amount of fibrinogen present in 1 unit of cryoprecipitate, the plasma volume, and the desired increment. The difficulty in determining the correct amount to administer is primarily caused by variability in the fibrinogen content of cryoprecipitate, and secondarily by variability in donors and component processing and preparation. The goal of therapy should be to maintain the measured fibrinogen at greater than 100 mL/dL, although some studies and consensus recommendations have revised target levels to at least 150 to 200 mg/dL, or a TEG maximum clot firmness (MCF) reading of 6 to 8 mm. It is estimated that each unit of cryoprecipitate raises the fibrinogen level of a 70-kg patient by at least 7 to 8 mg/dL; thus, a dose of 10 units of cryoprecipitate (equivalent of 1 blood volume's worth) will increase the fibrinogen in a 70 kg adult by 70 to 80 mg/dL, but how this dose affects a TEG is unclear. Dosing frequency should be determined based on clinical and laboratory responses; fibrinogen are very stable proteins with a half-life of 4 days.

Compatibility

Cryoprecipitate can contain minimal anti-A and/or anti-B antibodies and, as such, ABO and D compatibility is not necessary for most adult and pediatric patients. Cryoprecipitate does not need to be leukoreduced or irradiated.

Adverse Events

Cryoprecipitate has similar adverse event risk as other blood products, including transfusion-transmitted diseases and allergic reactions. Since it contains less plasma TACO and TRALI reactions are rare. Large volumes of ABO incompatible cryoprecipitate may cause a positive direct antiglobulin test.

PLASMA DERIVATIVES

Plasma derivatives, including albumin, human immune globulin (Ig), coagulation factor concentrates, are highly purified protein preparations that are obtained from large pools of whole blood or apheresis-derived plasma. The development of large-scale methods for the preparation of plasma derivatives began more than 70 years ago. There have been significant improvements in the preparation of these products since then, however the manufacturing is still based on modifications of the original method of cold ethanol fractionation, known as the Cohn fractionation process, developed by Dr. Edwin J. Cohn of Harvard Medical School and a team of scientists during the World War II era (Fig. 115.2).[1] Additional selective purification techniques involving ion exchange,[92] immune affinity chromatography, and other separation techniques are also used depending on the protein to be isolated and the individual manufacturer.[2]

Plasma contains thousands of different proteins and multiple products can be produced from a single raw material. Manufacturers begin by thawing frozen human plasma. During the Cohn's process, the ethanol concentration is serially increased and the precipitates and supernatants are separated by continuous-flow centrifugation or by large-scale filter presses. Fraction I, at 8% ethanol, yields the first precipitate in the fractionation process that contains fibrinogen and other poorly soluble proteins. Fractions II and III are then precipitated together and contain the immunoglobulins. Fraction IV-1 contains the vitamin K–dependent (VKD) clotting factors, antithrombin and α_1-proteinase inhibitor, whereas fraction IV-4 contains transferrin, haptoglobin, and some of the albumin. Fraction V is almost pure albumin (see Fig. 115.2).[1]

The extracted protein preparations are further subjected to additional steps (i.e. filtration, nanofiltration, solvent/detergent treatment, heat treatment, and pasteurization) to inactivate viruses and other infectious agents, making the risk of infectious disease transmission virtually zero.[93,94] The development of genetic engineering technology has allowed recombinant human plasma proteins to be produced in cell culture systems and transgenic animals.[95] This allows for greater control over the source of starting material, a reduction in the risk of infectious transmission from donors, and the easier production of a more uniform product with less variability. A description of select plasma derivatives is discussed below.

ALBUMIN

Albumin, an important plasma protein, contributes primarily to the maintenance of plasma colloid oncotic pressure. Also, it is involved in the transport of numerous substances, such as unconjugated bilirubin, hormones, and drugs. Additionally, albumin has an established role in acid-base function, free radical scavenging, is antiapoptotic, antithrombotic, and has positive and negative effects on vascular integrity. The human body content of albumin is 4 to 5 g/kg and is responsible for 80% of the osmotic pressure of plasma.[96] Albumin is clinically available in four forms: 5% albumin solution; 25% albumin solution; albumin conjugated with polyethylene glycol; and purified protein fraction, which is 5% total protein (88% albumin and 12% globulins). These products are heat-treated, and albumin has not been documented to transmit infectious diseases (single outbreak occurred with albumin transfusion-associated hepatitis B with purified protein fraction in 1973 due to a failure in manufacturing process).[97]

Indications

A decrease in measured plasma albumin is found in many situations including chronic liver disease, chronic renal failure, sepsis, malignancy, burns, critical illness, severe head trauma, and hemorrhage, and is often not a clinically significant concern. Mild edema arising from hypoalbuminemia does not require albumin therapy. However, inadequate synthesis, as seen in severe liver disease and severe malnutrition, or excessive loss, as seen in nephrotic syndrome and protein-losing enteropathy, can lead to significant hypoalbuminemia with intravascular volume depletion, anasarca, ascites, and pleural effusions. Hypoalbuminemia is associated with poor clinical outcome in some studies, yet correction of low serum albumin levels in critically ill patients does not improve outcome measures such as mortality, duration of intensive care unit (ICU) and hospital stay, or mechanic ventilation. Historically, albumin had a broader use (i.e., nutritional support, correction of hypoalbuminemia, volume replacement); however recent studies support its benefit in fewer situations, including nephrotic syndrome resistant to potent diuretic therapy, after large-volume paracentesis, and in ovarian hyperstimulation syndrome (OHSS) (Table 115.4).[96]

TABLE 115.4 Administration of Albumin

Indicated
After large-volume paracentesis
Nephrotic syndrome resistant to potent diuretics
Ovarian hyperstimulation syndrome
Volume/fluid replacement in plasmapheresis
Possibly Indicated
Adult respiratory distress syndrome
Cardiopulmonary bypass pump priming
Fluid resuscitation in shock/sepsis/burns
Neonatal kernicterus/hyperbilirubinemia
To reduce enteral feeding intolerance
Not Indicated
Correction of measured hypoalbuminemia or hypoproteinemia
Nutritional deficiency, total parenteral nutrition
Preeclampsia
Red blood cell suspension
Simple volume expansion (surgery, burns)
Wound healing
Investigational
Cadaveric renal transplantation
Cerebral ischemia
Stroke
Common Usages
Cardiopulmonary bypass, pump priming
Extensive burns
Hypotension
Intraoperative fluid requirement exceeding 5–6 L in adults
Labile pulmonary, cardiovascular status
Liver disease, hypoalbuminemia, diuresis
Nephrotic syndrome, proteinuria, and hypoalbuminemia
Plasma exchange
Premature infant undergoing major surgery
Protein-losing enteropathy, hypoalbuminemia
Resuscitation
Serum albumin <20 g/dL

Intravascular Volume Expansion

As noted, albumin provides most of the plasma colloid oncotic pressure. Infused albumin provides colloid oncotic pressure; however, 50% of the infused protein is lost to the extravascular fluid compartment within 4 hours. Crystalloid may also provide volume expansion and is more quickly redistributed into total body fluids. Studies investigating the use of albumin in various situations including volume expansion during and after surgery, as priming solution in cardiopulmonary bypass, or in maintaining colloid oncotic pressure, found no clinical benefit compared with controls. In 1998, the Cochrane Injuries Group performed a systematic review of randomized control trials in albumin treatment of critically ill patients and concluded that there was no evidence that albumin use for volume expansion reduces patient mortality. They also suggested that albumin increases mortality, but this conclusion was not confirmed in later randomized control trials or subsequent meta-analyses.[98] The SAFE trial found, in 6997 patients across 16 ICUs, that there was no difference in survival between those ICU patients who received albumin versus normal saline.[99] In another randomized study, the SAFE trial investigators found that albumin use was associated with a trend toward better outcomes in patients with severe sepsis 28 days post-randomization.[100] A smaller prospective study further revealed that albumin was at least equivalent to plasma in clinical endpoints (perioperative/postoperative RBC transfusions, postoperative blood loss, duration of ICU stay, major complications) as a plasma expander in the context of pediatric craniofacial surgeries.[101] One conclusion from these prospective randomized trials is, contrary to previous reports, that the use of albumin is at least clinically equivalent to saline or plasma for intravascular volume resuscitation in some clinical settings. Moreover, the Italian Society of Transfusion Medicine and Immunohematology recently recommended that albumin may be useful for hypovolemia in some patients with hemorrhagic shock, patients undergoing major surgery, such as cardiac surgery, patients with severe burns, and patients post-liver transplant when crystalloids and other colloids did not provide adequate clinical benefit.[96]

Hypoalbuminemia

Low serum albumin is an independent predictor of morbidity and mortality in many clinical settings. However, correction of low serum albumin levels in ill patients does not improve outcome measures such as mortality.[102] However, two randomized controlled studies showed that correction of hypoalbuminemia did improve respiratory, cardiovascular, and central nervous system function. Current guidelines support the use of albumin to correct hypoalbuminemia for patients with ascites, large volume paracentesis, hepatorenal syndrome, and spontaneous bacterial peritonitis.[103] Recent studies with albumin infusions have also been done in end-stage liver disease patients for hypoalbuminemia. However, results are less encouraging, with studies indicating no additional benefits or reduction in morbidity.

Cirrhosis

The use of albumin in cirrhotic patients dates to before 1950. In this setting, albumin was recommended for temporary improvement in hyponatremia, spontaneous bacterial peritonitis, or prevention of the complications associated with paracentesis, including volume shifts and hyponatremia. A single randomized control trial of albumin use in cirrhotic patients with spontaneous bacterial peritonitis revealed that albumin administration with antibiotics resulted in reduced mortality and a reduced risk of renal failure in comparison with antibiotic use alone. Several studies demonstrated that after large-volume paracentesis (LVP) (>5 L), hyponatremia and renal insufficiency were improved with albumin infusion compared with other volume-expanding agents.[104,105] However, a recently published meta-analysis found insufficient evidence that albumin infusion after LVP lowered mortality in patients without hepatocellular carcinoma but with advanced liver disease.[106]

Nephrotic Syndrome

Albumin has been used to increase colloid oncotic pressure with the intention of increasing diuresis via increasing vascular pressure at the level of the glomerulus. Several studies have shown that albumin use in this context has resulted in no clinical benefit.[107] However, other studies have suggested that albumin use is associated with increased hypertension, respiratory distress, and electrolyte abnormalities. Consequently, the current recommended use of albumin for nephrotic syndrome patients is limited to patients in whom diuretic therapy is poorly tolerated or ineffective or in those with massive ascites or anasarca.

Ovarian Hyperstimulation Syndrome

OHSS is usually a result of iatrogenic administration of human chorionic gonadotrophin (hCG) to induce ovulation. OHSS is typified by enlarged ovaries which release vascular endothelial growth factor that can result in increased capillary permeability. This, in turn, leads to a fluid shift out of the intravascular compartment to the abdominal/pleural spaces resulting in ascites and hypovolemia. In the most severe form, the patient can develop tense ascites, oliguria, dyspnea, hemodynamic instability, and thromboembolism. Treatment includes fluid restriction, analgesics, and close monitoring; occasionally, hospitalization may be necessary.

Mild OHSS occurs in approximately one-third and moderate-severe in approximately 5% of women receiving exogenous hCG. Increased risk of OHSS includes young age, low body weight, polycystic ovarian syndrome, high-dose hCG, high or rapid rise in estradiol level, and previous history of OHSS. In addition, the risk is proportional to the number of developing follicles and number of oocytes retrieved.[118] Moderate-severe OHSS can be mitigated by closely monitoring women during treatment and subsequently withholding or reducing hCG administration when there is a large number of intermediate-size developing follicles present or when estradiol levels are elevated.[109,110]

In 2011, the Cochrane collaboration systematically reviewed eight randomized clinical trials of albumin administration in OHSS and concluded that there is only a borderline statistically significant decrease in the incidence and severity of OHSS when albumin was administered during oocyte retrieval in high-risk women. In contrast, the meta-analysis further revealed that the use of hydroxyethyl starch (HES) resulted in a markedly decreased incidence of severe OHSS.[111] In addition, Bellver et al. published a large, randomized trial that demonstrated no difference in moderate-severe OHSS when 40 g of albumin was administered after the retrieval of 20 or more oocytes.[112] Only one (nonrandomized) study to date has compared human albumin and 6% HES. This study concluded in 16 patients with severe OHSS that patients who received HES had a higher urine output, needed less abdominal paracentesis and drainage of pleural effusions, and had a shortened hospital stay than patients who received albumin.[113] Therefore, while still clinically used, albumin may be inferior to other therapies in the prevention of OHSS.

Therapeutic Apheresis

Albumin is the replacement fluid of choice for many apheresis indications (see Chapter 116).[51] Albumin reduces the risk of adverse events during apheresis procedures by reducing the risk of viral transmission, allergic reactions, and TRALI in comparison to plasma use (see plasma section). Albumin can also be used in combination with saline during apheresis procedures, but excessive use of saline results in hypotensive reactions. Albumin is also indicated if large (>15% of the total blood volume) blood volumes are removed to prevent hypotensive reactions in other therapeutic or collection apheresis procedures (leukapheresis, plateletpheresis).

While albumin is generally well tolerated in therapeutic apheresis patients, albumin use can result in significant hypotension, bradycardia, and flushing in patients receiving angiotensin converting enzyme inhibitor (ACE) therapy. ACE inhibitors prevent the patient's ability to metabolize bradykinins that are present in the albumin and activated during the apheresis procedure. In patients taking ACE inhibitors, symptoms can be prevented by using plasma, or halting ACE inhibitor use and delaying the start of apheresis therapy.

Fluid Resuscitation in Sepsis/Burns

Serum albumin has been shown to be a free radical scavenger. Because of this function, some guidelines recommend albumin infusion when patients with sepsis or acute burns require a substantial amount of crystalloids. However, meta-analyses have demonstrated no significant difference in mortality from albumin compared to other fluids in patients with these conditions.[17,114–118]

Dose

The volume and speed of administration should be determined by the patient's volume status, condition, and response to the product.[119] In an adult, the total daily dose should not exceed the theoretical amount present in normal plasma (2 g/kg/day), in the absence of acute hemorrhage. In the pediatric population, albumin dose again depends on the patient's condition, but 0.5 to 1.0 g/kg/dose with a maximum dose of 6 g/kg/day is used as a general guideline. Albumin 5% is oncotically equivalent to normal human plasma. Albumin 25% provides less infusion volume per amount of albumin and is usually administered to patients with fluid or sodium intake restriction. Albumin 25% expands the blood volume by 3.5 times by drawing fluid into the intravascular space.

Adverse Effects

Albumin is a plasma derivative used widely and associated with rare adverse reactions.[103] Allergic reactions, including urticaria, may be encountered.[119] Changes in vital signs (heart rate, blood pressure, respiration rate), nausea, emesis, and fever/chills have also been rarely reported. Volume overload and dilutional anemia as well as hypocalcemia may occur. In addition, hypotensive and allergic reactions have been associated more frequently with the use of plasma protein fraction than purified albumin. Albumin has not been associated with transfusion-transmitted diseases.

HUMAN IMMUNOGLOBULIN

Human immunoglobulins (Ig) are prepared by fractionation of large pools of human plasma.[96] There are numerous preparations available in the US and worldwide. Ig preparations can be made for intramuscular (IM), subcutaneous (SC), or intravenous (IV) administration. Each preparation is slightly different and has theoretic advantages and disadvantages and specific licensed indications. Ideally, Ig preparations should contain each IgG subclass; retain Fc receptor activity; have a normal half-life; demonstrate virus neutralization, opsonization, and intracellular killing; and have antibacterial capsular polysaccharide antibody.[120] Furthermore, vasoactive impurities should be absent, and no transmissible infectious agents should be present. The uses of Ig have been extensively reviewed elsewhere (see reference section) and the number of theoretical and accepted uses is rapidly expanding.

Indications

Human Ig is indicated for replacement of Igs or for its immunomodulatory effects.[121] Currently, there are six FDA approved indications for IVIg treatment: primary immunodeficiency, B-cell chronic lymphocytic leukemia (CLL) with infection, chronic inflammatory demyelinating polyradiculoneuropathy (CIPD), immune thrombocytopenia (ITP), Kawasaki disease, and multifocal motor neuropathy. IVIg is also considered first-line therapy for multiple other conditions, such as allogeneic stem cell transplantation, Guillain-Barré syndrome, neonatal alloimmune thrombocytopenia (NAIT), posttransfusion purpura (PTP), myasthenia gravis and stiff-person syndrome (Table 115.5). A brief summary of some of the more well-established uses of IVIg is presented in the following section.

Primary or Secondary Immune Deficiencies

Primary congenital immunodeficiency syndromes have been treated with intramuscular Ig for the past 30 years. The use of intramuscular Ig has certain disadvantages: delayed absorption, delivery of inadequate amounts because of small muscle mass, and pain at the

TABLE 115.5 **Administration of Intravenous Immunoglobulins**

Indicated
Ataxia-telangiectasia
Chronic inflammatory demyelinating polyneuropathy
Chronic lymphocytic leukemia
Common variable immunodeficiency
Cytomegalovirus-interstitial pneumonia after bone marrow transplantation
Guillain–Barré syndrome
Graft-versus-host disease after bone marrow transplantation
Hemolytic disease of the fetus and newborn
Idiopathic thrombocytopenic purpura
Immunoglobulin G subclass deficiency
Inflammatory myopathies (refractory dermatomyositis and polymyositis)
Myasthenia gravis
Mucocutaneous lymph node syndrome (Kawasaki disease)
Neonatal alloimmune thrombocytopenia
Parvovirus infection
Persistent deficit in antibody production after bone marrow transplantation
Posttransfusion purpura
Primary immunodeficiency syndromes
Secondary hypogammaglobulinemia
Severe combined immunodeficiency
Stiff-person syndrome
Wiskott-Aldrich syndrome
X-linked agammaglobulinemia
Possibly Indicated
Antiphospholipid syndrome in pregnancy
Autoimmune hemolytic anemia (warm type unresponsive to prednisone)
Factor VIII inhibitors (refractory)
Graves ophthalmopathy
Immune neutropenia
Multiple myeloma (stable disease, high risk for infections)
Pemphigus
Solid organ transplantation (kidney)
Systemic lupus erythematosus (refractory, severe, active)
Thrombocytopenia refractory to platelet transfusion
Vasculitis (refractory to standard therapy)
Investigational
Acquired von Willebrand disease
Amyotrophic lateral sclerosis
Burn patients
Chronic fatigue syndrome
Chronic human parvovirus B19 infection
Chronic idiopathic pericarditis
Chronic pain syndromes
Congestive heart failure
Dilated cardiomyopathy
Graft-versus-host disease
Human immunodeficiency virus infection
Immune-mediated aplastic anemia
Inflammatory bowel disease
Intractable childhood epilepsy
Multiple sclerosis
Myocarditis
Necrotizing fasciitis
Neonatal sepsis
Neonatal hemochromatosis
Postpartum cardiomyopathy
Prevention of nosocomial postoperative infections
Prophylaxis in transplant recipients against cytomegalovirus infection
Recurrent unexplained spontaneous abortions
Rheumatoid arthritis
Sepsis and septic shock
Toxic epidermal necrolysis/Stevens-Johnson syndrome
Toxic shock syndrome

injection site. IVIg overcomes these disadvantages and used prophylactically in patients with primary immunodeficiency has been demonstrated to reduce the number of febrile and infectious episodes as well as improve survival rate.[122] IVIg use in IgG subclass deficiencies is also beneficial. The typical maintenance dose for adults is 400 to 600 mg/kg every 3 to 4 weeks to maintain a trough IgG level of at least 500 mg/dL. SC Ig administration is now also FDA-approved for use in primary immunodeficiency treatment. Secondary/acquired immune deficiency may be caused by multiple etiologies including hematologic malignancy (e.g., CLL, multiple myeloma, protein-losing enteropathy, nephrotic syndrome, or other severe illnesses). Criteria for the use of IVIg in these conditions include hypogammaglobulinemia (IgG < 200 or total Ig < 400 mg/dL), absent or low natural antibodies, absent or low response to antigenic challenge (i.e., vaccines), and lack of antibody response to the infecting organism.

B-Cell Chronic Lymphocytic Leukemia With Infection

CLL may be associated with hypogammaglobulinemia and complications of repeated bacterial infections.[123] These infections are the most common cause of morbidity and mortality in CLL patients. The administration of Ig preparations may replace the missing immunoglobulins needed for humoral immunity. However, due to recent advances in management and treatment for CLL patients, IVIg should only be considered for those with recurrent serious bacterial infections and serum IgG levels less than 500 mg/dL despite immunization to diphtheria, tetanus, or pneumococcus. A typical dose of 300 to 500 mg/kg per month is needed to maintain a minimum IgG level of 500 mg/dL.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

CIDP is a chronic disorder resulting in demyelination of peripheral nerves that result in weakness and sensory changes. Equivalent outcomes have been observed after treatment with IVIg (reported dose 2 g/kg/day over 2 to 5 days, once each month), TPE, or corticosteroids.[124] The decision as to which treatment to use is made on an individual basis balancing the risks and benefits of each treatment modality.

Immune Thrombocytopenia

IVIg and Rh immune globulin (RhIg, described below) are routinely and effectively used in the treatment of acute and chronic ITP.[125] IVIg significantly raises the platelet count within 5 days in adults with chronic ITP and in children with acute ITP. The mechanism of action of IVIg in ITP is unknown; one postulation is Fc receptor blockade decreases the removal of antibody-coated platelets. Other proposed mechanisms include suppressed antiplatelet antibody synthesis, increased antiviral immunity, and blockage by anti-idiotypic antibodies. In general, IVIg induces responses in most patients within 1 to 2 days. Responses are of variable duration and are rarely sustained, although maintenance therapy may be of some value. IVIg may be effective in chronic ITP refractory to corticosteroids or splenectomy, and may show greater efficacy in conjunction with corticosteroids.

Although IVIg has shown equal efficacy with corticosteroids in pediatric acute ITP and in 75% of adults with chronic ITP, because of the transient responses and high cost, its use is justified only in clinical situations requiring rapid elevation of platelet count or if standard therapy has failed. IVIg is, therefore, indicated in acute bleeding episodes or before urgent surgery, including splenectomy; in patients at high risk of intracranial hemorrhage; and in those in whom corticosteroids are contraindicated or ineffective. IVIg has also been used to treat ITP during pregnancy, postinfectious thrombocytopenia, ITP associated with HIV infection, and neonatal thrombocytopenia (see Chapter 129).

Kawasaki Disease

Mucocutaneous lymph node syndrome (Kawasaki disease) has been treated with aspirin with or without concomitant IVIg administration. Coronary artery aneurysm, a serious complication of this disease, was significantly reduced in the IVIg-treated group. However, in a multicenter retrospective survey of all children treated with Kawasaki disease, persistent or recrudescent fever after their first course of IVIg was associated with a statistically significant risk of treatment failure. Furthermore, IVIg retreatment in those patients with persistent fever after IVIg treatment failure was approximately 60%.[126] Current randomized trials are now being done to compare the efficacy of newer, and perhaps better, therapies, such as infliximab (anti-tumor necrosis factor-α).[127] To date, these randomized control studies show that infliximab is at least as safe and as efficacious as IVIg in these refractory patients. One retrospective review has even suggested that infliximab might result in faster resolution of fever and fewer days of hospitalization in comparison with IVIg. While studies are still ongoing, IVIg may soon be replaced by alternative therapies in this refractory patient population.

Regarding the pathogenesis of Kawasaki disease, decreased peripheral blood lymphocyte apoptosis has been demonstrated.[128] Therefore, the effect of IVIg in Kawasaki disease has been postulated to partially reverse inhibited lymphocyte apoptosis.

An important related disorder is COVID-19-associated multi-inflammatory syndrome in children (MIS-C), which involves at least four organ systems and occurs after infection with COVID-19. IVIg is the most common treatment.[129]

Multifocal Motor Neuropathy

Multifocal motor neuropathy is a chronic progressive disorder resulting in primarily hand weakness. IVIg (SC administration under investigation) is now considered a first-line treatment for this condition,[130,131] and improved strength can be seen at a dose of 2.0 g/kg over 2 to 5 days.

Hematopoietic Stem Cell Transplantation

The use of prophylactic IVIg or cytomegalovirus (CMV)–IVIg in CMV-negative hematopoietic stem cell transplant (HSCT) recipients during the first 100 days posttransplant has been demonstrated to reduce the incidence of symptomatic CMV-associated disease, including CMV interstitial pneumonia, in some trials.[132] Because of the high cost of this treatment and the increasing use of prophylactic ganciclovir, IVIg is currently not indicated for the routine prophylaxis of CMV infections in HSCT recipients. IVIg should be given to allogeneic HSCT recipients with IgG less than 400 mg/dL and with recurrent infections.[133] In established CMV-interstitial pneumonia, IVIg in combination with ganciclovir has been shown to reduce the mortality rate and has become the recommended treatment modality. IVIg's role in preventing severe graft-versus-host disease is unclear.[134] Prolonged IVIg therapy during graft-versus-host disease prevention may suppress humoral immunity recovery.

Solid Organ Transplantation

The presence of high-titer reactive antibodies against incompatible graft HLA or ABO antigens increases the risk of early solid organ, antibody-mediated, graft rejection and mortality, especially in kidney and cardiac transplants. For some patients who have HLA antibodies to undergo transplantation, these antibodies must be removed or decreased. While morbidity and mortality can be reduced by selecting an adequately cross-matched donor, IVIg with or without plasma exchange and with or without rituximab has also been shown to decrease sensitization of incompatible antigens in patients awaiting renal and cardiac transplantation.[135] In addition, IVIg combined with rituximab and with or without TPE is used in the treatment of biopsy-proven antibody-mediated rejection. Consensus as to the appropriate treatment regimen, IVIg ± TPE ± rituximab, for incompatible solid organ transplants, is still under investigation.

Randomized trials have not yet been performed for ABO-incompatible heart, liver, or lung transplants. Moreover, there is a paucity of data for transplant outcomes, and current studies have small numbers of patients without data on donor-specific antibody levels.

Aplastic Anemia Secondary to Parvovirus

Parvovirus B19 infection can result in severe anemia and reticulocytopenia, especially in immunocompromised individuals[136] or individuals with sickle cell disease or thalassemia, and the use of IVIg is considered first-line therapy in the treatment of these patients (typical dose 0.5 g/kg weekly for 4 weeks).

Dermatomyositis

Dermatomyositis is a chronic inflammatory disorder that results in progressive weakness and rash. IVIg (typical dose 2.0 g/kg per month administered over 2 to 5 days) results in improved muscle strength and neuromuscular symptoms.[137]

Guillain-Barré Syndrome (Acute Inflammatory Demyelinating Polyneuropathy)

Guillain-Barré syndrome is an acute demyelinating peripheral neuropathy affecting both motor and sensory nerves. IVIg (typical dose 400 mg/kg/day for 5 days or 1.0 g/kg/day for 2 days or 2.0 g/kg as a single dose) is likely equivalent to TPE in improving disability and shortening the time to improvement.[138]

Hypogammaglobulinemia Associated With Multiple Myeloma

Multiple myeloma is a monoclonal B-cell (plasma cell) disorder with clinical symptoms arising as a result of plasma cell infiltration of the bone marrow, monoclonal Ig in the blood and urine, and immunosuppression. IVIg (SC administration under investigation) has shown to be beneficial in preventing serious infections in plateau-phase multiple myeloma or other hematologic malignancy, where the patients have hypogammaglobinemia, at doses of 0.4 g/kg every 4 weeks, with subsequent dosing adjusted based on trough levels.[138]

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome results from antibodies to the neuromuscular junction, leading to autonomic dysfunction. One randomized control trial revealed that IVIg significantly improves generalized central and peripheral muscle strength and decreases serum calcium channel antibody titers. A total dose of 2.0 g/kg given over 2 to 5 days is a recommended initial treatment.[137]

Multiple Sclerosis

Multiple sclerosis is a chronic progressive or relapsing and remitting disorder characterized by brain white matter demyelination. There are two published meta-analyses,[140,141] and several randomized controlled clinical trials[142] in patients with relapsing-remitting multiple sclerosis using a wide range of IVIg doses that demonstrate the success of IVIg in reducing the number of exacerbations and disability in patients with relapsing-remitting multiple sclerosis in comparison with placebo. However, no studies to date have compared IVIg with standard therapies, and one clinical trial (PRIVIG trial)[143] has raised doubt that IVIg is effective as a routine treatment. Consequently, IVIg is considered a viable second-line option for those patients who fail, decline, or are unable to tolerate standard immunomodulatory therapies such as β-interferon and glatiramer acetate.

Myasthenia Gravis

Myasthenia gravis is a chronic neurologic autoimmune disorder characterized by weakness and fatigue upon repetitive skeletal muscle use, which improves with rest.[144] IVIg has been used successfully as a short-term measure for acute severe exacerbations of myasthenia gravis at a dose of 2.0 g/kg given over 2 to 5 days and outcome is comparable to treatment with TPE.[145]

Neonatal Alloimmune Thrombocytopenia

NAIT is a rare condition that results from maternal platelet alloantibodies against the fetal/neonatal platelets resulting in neonatal/fetal thrombocytopenia.[146] Studies evaluating the use of IVIg for NAIT are limited because of the rarity of the condition. The treatment of NAIT during pregnancy is maternal administration of 1.0 g/kg IVIg weekly as a first-line therapy beginning at 20 weeks of gestational age with the use of corticosteroids, or 2.0 g/kg weekly if steroids are not used.[147] Once at 32 weeks of gestation, the IVIg dose is increased to 2.0 g/kg weekly with corticosteroids. Moreover, the neonate may need to receive IVIg and platelet transfusions after delivery to increase fetal platelet counts to prevent intracerebral hemorrhage at a dose of 1.0 g/kg (see Chapter 129).

Hemolytic Disease of the Fetus and Newborn

Hemolytic disease of the fetus and newborn (HDFN) results from maternal RBC alloantibodies binding to fetal/neonatal RBCs and may result in hemolysis, leading to anemia or hydrops fetalis and death depending on the severity. Maternal IVIg infusion (with or without TPE) has been used in severe cases of HDFN where treatment must occur before the ability to perform intrauterine transfusions. After delivery, IVIg has been suggested to significantly reduce the need for exchange transfusions in neonates with HDFN, although there have been conflicting results in randomized controlled trials.[148] In addition, IVIg treatment of HDFN has been associated with increased risk of necrotizing enterocolitis in the neonate. IVIg is now consequently recommended at a dose of 0.5 g/kg to treat newborns with HDFN if there is established jaundice and a rising total serum bilirubin despite phototherapy.[149]

Posttransfusion Purpura

PTP is a rare complication of transfusion resulting in acute, profound thrombocytopenia, secondary to platelet antibodies that destroy both transfused and autologous platelets. While the evidence evaluating the effect of IVIg in these patients is limited to multiple case reports, the available evidence suggests that IVIg should be a first-line therapy in this condition. PTP treatment with IVIg at a dose of 2 g/kg over 2 days or 0.4 to 0.5 g/kg daily for 5 days with or without corticosteroids can result in a rapid increase in platelet count.[150]

Sepsis and Septic Shock in Adults

The use of IVIg in adult patients with bacterial sepsis or septic shock is potentially beneficial. One randomized control trial revealed that in ICU patients with sepsis and shock, IVIg with antibiotics was superior to antibiotics with albumin in improving patient survival.[151] Encouraging results have also been identified in patients receiving

IVIg for streptococcal toxic shock syndrome, but further studies are currently needed.

Stiff-Person Syndrome

Stiff-person syndrome is a neurologic disorder associated with truncal and limb rigidity and heightened sensitivity. One small, randomized control trial suggests that IVIg could play a positive role in improving stiffness and sensitivity symptoms. Currently, IVIg is considered a second-line therapy for those who fail or cannot tolerate GABA (glutamic acid decarboxylase)-ergic medications. A dose of 2.0 g/kg given over 2 to 5 days is the current recommended starting dose.[136]

Dosage

The FDA has approved IM, IV, and more recently SC Ig products. The dosage and frequency for each Ig product vary significantly depending on patient's age and clinical indication. Typical dosages were described in the preceding section. In general, patients require 200 to 800 mg/kg intravenously every 3 to 4 weeks to achieve adequate IgG levels if immunodeficient (usually 500 mg/dL) and needing protection against infection. Initially, serial IgG level determination may allow the physician to individualize the dose and schedule. These are affected by the recovery, half-life, redistribution, and catabolism of Ig preparation, which vary from product to product and patient to patient. Currently, direct comparisons between different IVIg formulations or brands are lacking, and so evidence-based recommendations cannot be made at this time.

Adverse Effects

Infusions of IVIg should be started slowly and patients should be closely monitored. If the initial rate (0.5 mL/kg/h) is well tolerated, the rate can be increased gradually, but not more than eightfold. That said, initial and maximum infusion rates vary by IVIg product, and product inserts should be consulted prior to selecting an appropriate infusion rate. Fever, headache, nausea, vomiting, fatigue, backache, leg cramps, urticaria, flushing, elevation of blood pressure, and thrombophlebitis may be seen.[152] Adverse events have been reported in 2% to 10% of infusions. Adverse reactions differ among different preparations, such that patients may tolerate one product better than another product. IgA-deficient patients may have IgG anti-IgA antibodies, which can cause anaphylactic reactions. This complication is rare and may be avoided by using products with a lower concentration of IgA. Aggregated IgG may produce chills, nausea, flushing, chest tightness, and wheezing. Rarely, IVIg preparations contain RBC antibodies that can produce hemolysis or interfere with serologic evaluations, including RBC compatibility testing. IVIg treatment will produce a false positive direct antiglobulin test, and sometimes positive hepatitis and CMV serologies. Serum sickness can also occur. Lastly, high-dose IVIg therapy has been associated with thrombosis, reversible acute renal failure, TRALI, and aseptic meningitis. Improved manufacturing processes currently in place render IVIg free of enveloped and nonenveloped viruses.

Tetanus immunoglobulin
Vaccinia immunoglobulin
Varicella-zoster immunoglobulin
Western equine encephalitis immunoglobulin

HYPERIMMUNE IMMUNOGLOBULIN PRODUCTS

Hyperimmune globulins (Hyper-Ig) are concentrated Igs with specificity for an antigen or group of antigens.[153] These products are manufactured in a similar manner to that used for IVIg product production. However, donors for these specific products are unique in that they have high titers for the Ig specificity of interest. The donor high titers can be achieved via natural immunity, prophylactic immunization, or target immunization, depending on the antibody of interest. These products are generally used to provide passive immunity for a variety of conditions that are described in more detail in the following sections (Table 115.6).

Antithymocyte Globulin

Antithymocyte globulin is a purified concentrated globulin made from hyperimmune serum of horses immunized with human T lymphocytes. Antithymocyte globulin is used in renal transplant patients as an adjunct therapy in the treatment of graft rejection.[154] It is also used in patients with aplastic anemia who are not candidates for bone marrow transplantation.[155]

Infection-Associated Hyperimmune Immunoglobulin

Hyper-Ig is used to prevent the development of specific clinical disease or alter its symptomatology.[156] Hepatitis B Ig is used to provide passive immunity to hepatitis B virus associated with needle-stick exposure or sexual contact with hepatitis B surface antigen-positive individuals, post liver transplantation for prevention of recurrence, and prevention of hepatitis B vertical transmission. Other hyperimmunoglobulins include botulism, CMV,[157] hepatitis A, rabies,[158] respiratory syncytial virus, tetanus, vaccinia, and varicella-zoster virus Igs. Convalescent plasma can be made into hyperimmune Igs, which is being explored for treatment of COVID-19.[159]

WEAK, PARTIAL D, AND RhIg USE

Clinically significant D sensitization potentially results in a pregnancy with a fetus at risk for hemolytic disease of the fetus and newborn[161] and hemolytic transfusion reactions if transfused with D-positive red blood cells. In rare cases, as a result of a mutation in the *D* gene, a person may have amino acid substitutions affecting a part of the normal D protein that changes the antigen on the external aspect of the red blood cell. These patients are described as having "partial D." When someone with partial D is exposed to blood from someone with a normal form of D, they may make an antibody against the portions of the D antigen that they lack. Individuals with red blood cells that express a partial D antigen are thus at risk for D-sensitization and may benefit from RhIg administration to prevent D sensitization. Mutations which result in fewer "normal" D antigens on a red cell are known as having a "weak" D. Those with weak D antigens are usually not at risk for D sensitization because they have a normal D protein, and thus do not require RhIg administration. Partial and weak D antigens cannot be distinguished by serologic reactivity. However, reagents are manufactured that the most frequent partial D phenotypes give weak reactions. If a patient has weak or variable D typing, particularly in the prenatal setting, RhD genotyping can be done to distinguish weak D from partial D to help determine need for RhIg administration.[161,162]

Dosage

In general, formulations for the described hyper-Ig are generally prepared for IM administration but, in some instances, IV formulations are available. Refer to manufacturer's instructions for recommended dose and frequency of specific hyper-Igs as differences exist between formulations and for different conditions.

Rh Immunoglobulin

Rh immunoglobulin (RhIg) has two primary indications: prevention of D antigen alloimmunization and treatment of ITP.[160] It is given to D-negative mothers after potential exposure to fetal D-positive RBCs, such as after abortion or amniocentesis, as well as at 28 weeks gestational age, and postpartum if the child proves to be D positive.[161] The therapeutic effect is thought to be caused by antibody feedback with T-cell suppression of the B-cell clone responsible for the formation of anti-D antibody. (See box on Weak, Partial D, and Rh Ig Use.) RhIg can also be given to prevent immunization in D-negative individuals given D-positive blood products, such as platelets.[159,160] RhIg preparations are intended for either IM or IV administration.

Dosage

RhIg is dosed to adequately prevent D immunization. In the United States, 300 µg are administered after event resulting in maternal-fetal hemorrhage, 28 weeks and postpartum. Doses are increased for evidence of large maternal-fetal hemorrhage (300 µg for every 15 mL of RBC exposure). Factional calculated doses should be rounded to the next whole number. This dosing is also used in the prevention of D alloimmunization after receipt of RBC-containing blood product.[166] RhIg should be given within 72 hours after RBC exposure. Dosing can vary slightly by manufacturer. IV RhIg use in ITP is indicated in D-positive patients with intact spleen. It has been suggested that the mechanism of action may involve a shift in the immune-mediated destruction from platelets to the antibody-coated RBCs.[167] RhIg doses are substantially higher for the treatment of ITP: 50 µg/kg for hemoglobin ≥10 L/dL and 25 to 40 µg/kg when hemoglobin is 8 to 10 g/dL.

Adverse Effects

Adverse effects similar to those associated with IVIg can occur with use of hyper-Igs. Local adverse reactions such as tenderness, pain, soreness, or stiffness of the muscle may occur at an IM injection site. Individual hyper-Ig products have adverse effects specific to them. Animal derived hyper-Igs carry a risk of serum sickness. At low doses of RhIg, such as those used to prevent D immunization, fever, chills, and rarely hypersensitivity reactions are noted. Hemolysis, DIC, and rarely death have occurred with high doses of RhIg used to treat ITP.

COAGULATION FACTOR CONCENTRATES

Historically, the major source of coagulation factors for treatment of congenital deficiencies was plasma or cryoprecipitate. Plasma fractionation, along with improved testing and processing, has led to highly purified plasma-derived coagulation factor concentrates that have dramatically increased the quality of life and life expectancy for patients. In addition, recombinant products without human proteins can be produced in modified forms that may give them advantageous new properties. Each coagulation factor product differs in its composition, major indication, and dosage. The development of improved coagulation factor concentrates, as well as other therapies, continues to be a major focus of research.[168]

Recombinant Factor Concentrates

With the advent of genetic and cellular engineering technologies, it is possible to isolate the genes of specific coagulation factors, such as factor VIII, and to artificially produce properly functioning protein from cell culture. Almost all plasma proteins licensed for human use have been cloned and manufactured in biologically active form in the laboratory. The main advantages of recombinantly produced proteins include freedom from human viruses and a potentially unlimited supply, as reliance on blood donation is no longer needed.[169–171]

Recombinant proteins can also be produced in modified forms that may give them advantageous new properties such as increased potency, longer half-lives, or varied specificity. For example, some manufacturers are connecting factor VIII to another molecule that has a longer half-life such as albumin or an immunoglobulin fragment. This reduces the frequency of product infusions from every other day to once every 3 to 5 days.[172] Recombinant technology can design completely new proteins that do not occur in nature, such as B domain-deleted factor VIII. Research has shown that the B domain of factor VIII is not necessary for coagulant activity.[173] Eliminating the B domain increased the expression of the factor VIII molecule as much as 20-fold compared to the full-length factor. For patients with antibodies against human factor VIII recombinant porcine factor VIII is often indicated as antibodies do not often react to porcine factor, but the porcine molecule is active in the human coagulation process.

The use of plasma-derived clotting factor concentrates, and coagulation factor concentrates that are genetically engineered as therapy for specific clotting factor deficiencies, are discussed in detail in Chapter 136, Transfusion Therapy for Coagulation Factor Deficiencies.

Dosage

The appropriate factor concentrate is dictated by each patient's factor deficiency, but the selection of a specific product is often a function of product availability and clinician/patient preferences.[174] Before prescribing a coagulation factor concentrate, the specific details of its dosing, half-life, and other pharmacokinetic characteristics should be reviewed from the most current version of the drug product's package insert.

While factor concentrate manufacturers often suggest doses that are weight-based, these recommendations are often based on the in vivo recovery of circulating factor activity in normal nonbleeding test subjects. Thus, it is recommended that pre- and post-infusion samples be collected from the patient for the first few administrations to determine the in vivo circulating factor activity recovery, which can help guide optimal dosing of subsequent infusions in order to maintain the factor levels at or above a desired threshold. Replacement factor therapy must consider the patient's current and projected risk of bleeding.

CHAPTER 116

HEMAPHERESIS

Kamille A. West and Harvey G. Klein

Therapeutic bloodletting is an ancient therapy that dates back to the Galenic conceptualization of illness caused by the imbalance of the four humors. The practice remained fashionable, albeit unproved, well into the 19th century. About the time that scientific skepticism began to temper the widespread use of therapeutic phlebotomy, a new technique for blood removal, apheresis, appeared in the research laboratory.[1] The term *apheresis*, derived from a Greek verb meaning "to take away or withdraw," was coined to describe removal of one component of blood with return of the remaining components to the donor. Like phlebotomy, apheresis was used first to treat patients but later became more important for collecting blood components for transfusion. In 2017, about 1.8 million units (14.6%) of red blood cells (RBCs), 2.2 million units (91.3%) of platelets, 350,000 units (10.8%) of plasma, and 4000 granulocyte doses were collected by apheresis in the United States.[2] The Plasma Protein Therapeutics Association estimates that 40 million liters of source plasma are collected annually by plasmapheresis in approximately 30 million collections. Apheresis plasma is critical for preparing plasma-derived medicinal products such as intravenous immunoglobulin (IVIg) and albumin. Increasingly, apheresis techniques are also used to collect cells from the peripheral blood of healthy donors and patients for hematopoietic stem/progenitor cell (HSPC) transplantation and for manufacturing immune cell therapies such as chimeric antigen receptor (CAR) T cells. More than 50,000 HSPC and cellular therapy products are collected at hospital and blood center apheresis facilities annually.[3] In clinical settings, apheresis may also be employed in a therapeutic context to treat disease by removing pathologic cells or plasma-bound substances. Therapeutic applications of apheresis will constitute the focus of this chapter.

PRINCIPLES OF APHERESIS

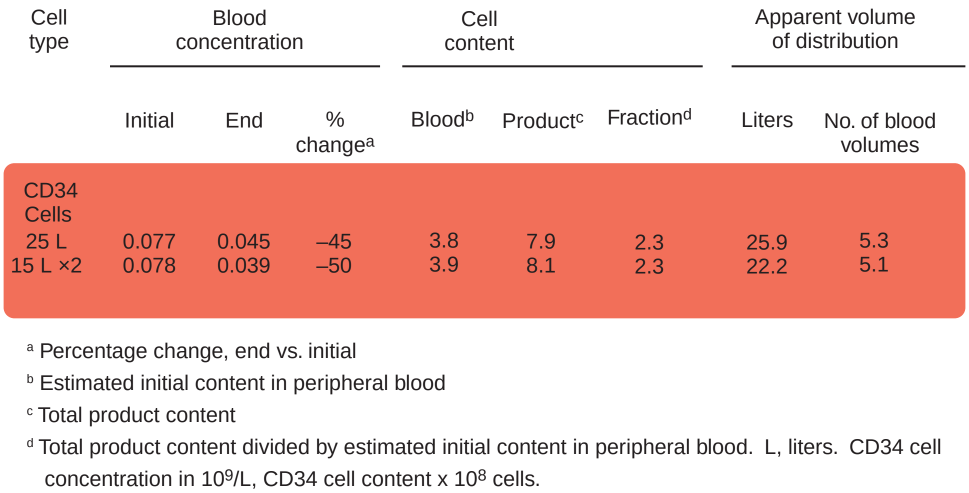
The principal objective of apheresis is efficient removal of some circulating blood component, either cells (cytapheresis) or some plasma solute (plasmapheresis). For most disorders, the treatment goal is to deplete the circulating cell or substance directly responsible for the disease process. Apheresis can also mobilize cells and plasma components from tissue depots. For example, lymphocytes may be mobilized from the spleen and lymph nodes of some patients with chronic lymphocytic leukemia (CLL), and low-density lipoproteins (LDLs) can be removed from tissue stores in patients with familial hypercholesterolemia. The apheresis procedure itself mobilizes $CD34^+$ cells from extravascular depots during peripheral blood HSPC donation, resulting in collection of more than twice as many $CD34^+$ cells than estimated based on preapheresis peripheral blood cell counts (Fig. 116.1). Apheresis may have other, less obvious effects. Lymphocyte depletion may modify immune responsiveness in some disease states, possibly by disturbing the control mechanisms of cellular immune regulation. Plasmapheresis enhances splenic clearance of immune complexes in certain autoimmune disorders. When therapeutic effect is judged by clinical improvement rather than by efficiency of solute removal, apheresis is more often a helpful adjunct than a form of first-line therapy.

Several mathematical models formulated for different clinical conditions describe the kinetics of apheresis. Removal of most blood constituents follows a logarithmic curve (Fig. 116.2). This model assumes that the substance removed is neither synthesized nor degraded substantially during the procedure, remains within the intravascular compartment, and mixes instantaneously and completely with any plasma replacement solution. When the goal of plasmapheresis is to supply a deficient substance, for example, the cleavase ADAM metallopeptidase with thrombospondin type 1 motif 13 (ADAMTS13) in the treatment of thrombotic thrombocytopenic purpura (TTP), replacement follows logarithmic kinetics similar to those developed for solute removal. Removal of 1.5 to 2.0 volumes will reduce an intravascular substance by approximately 80% (see Fig. 116.2); processing larger volumes results in little additional gain. Specific cell removal with centrifugal automated cell separators depend on the number of cells available, the volume of blood processed, the efficiency of the particular instrument, and the separation characteristics of the different cells. Most commercially available instruments remove platelets and lymphocytes extremely efficiently. Granulocytes and other mononuclear cells, including HSPCs from peripheral blood, cannot be cleanly separated from other cells by standard centrifugal apheresis equipment (Fig. 116.3). Optimal harvesting of these cells requires special techniques such as stimulating the donor with corticosteroids, cytokines or chemokine receptor antagonists, or adding sedimenting agents to enhance cell separation.

Whereas this model accurately estimates removal of cells and large proteins such as fibrinogen and immunoglobulin (Ig) M, removal of smaller solutes such as IgG and albumin-bound drugs are less efficient. Transfer of these moieties from the extravascular to the intravascular compartment depends both on diffusion along a concentration gradient and on active transport. The rate of clearance can be calculated using diffusion coefficients, sieving coefficients, and lymphatic flow rate, although in practice this degree of accuracy is rarely necessary.

TECHNOLOGY AND TECHNIQUES

Over 100 years ago, animal experiments formed the theoretical and practical basis for all modern extracorporeal blood purification methods. The plasmapheresis technique that originated in the animal laboratory required manual resuspension of RBCs and posed a substantial risk of microbial contamination of the components being reinfused. With the introduction of sterile, disposable, interconnected plastic blood bags, plasmapheresis became relatively safe and easy. However, manual apheresis proved too inefficient and labor intensive for collecting large component volumes, and raised concerns that the separated units of RBCs might be reinfused accidentally into the wrong donor or patient. The introduction of automated online blood cell separators solved these problems. Automated apheresis instruments use microprocessor technology to draw and anticoagulate blood, separate components either by centrifugation or by filtration, collect the desired component, recombine the remaining components for return to the patient or donor, and document procedure data. The equipment contains disposable plastic software in the blood path and uses anticoagulants containing citrate or combinations of citrate and heparin that do not result in clinical anticoagulation of the patient or donor. Most instruments function well at blood flow rates of 30 to 80 mL/min, and can operate from peripheral venous access or from a variety of multilumen central venous catheters.[4] Newer therapeutic apheresis devices are smaller and more automated, allowing for implementation of more safety functions and improved portability.



Cell type	Blood concentration			Cell content			Apparent volume of distribution	
	Initial	End	% change^a	Blood^b	Product^c	Fraction^d	Liters	No. of blood volumes
CD34 Cells								
25 L	0.077	0.045	–45	3.8	7.9	2.3	25.9	5.3
15 L ×2	0.078	0.039	–50	3.9	8.1	2.3	22.2	5.1

[a] Percentage change, end vs. initial

[b] Estimated initial content in peripheral blood

[c] Total product content

[d] Total product content divided by estimated initial content in peripheral blood. L, liters. CD34 cell concentration in 10^9/L, CD34 cell content x 10^8 cells.

Figure 116.1 Twenty healthy mobilized donors underwent either a single large volume leukapheresis procedure of 25 L or two consecutive-day smaller volume procedures of 15 L each. In both study groups, more than twice as many CD34 cells were collected than the estimated total content of these cells in the peripheral blood before apheresis, providing evidence for the existence of a large extravascular pool of peripheral blood stem cells, which becomes accessible to collection by leukapheresis. *(Modified from Bolan CD, Carter CS, Wesley RA, et al. Prospective evaluation of cell kinetics, yields and donor experiences during a single large-volume apheresis versus two smaller volume consecutive day collections of allogeneic peripheral blood stem cells. Br J Hematol. 2003;120:801, by permission of the authors.)*

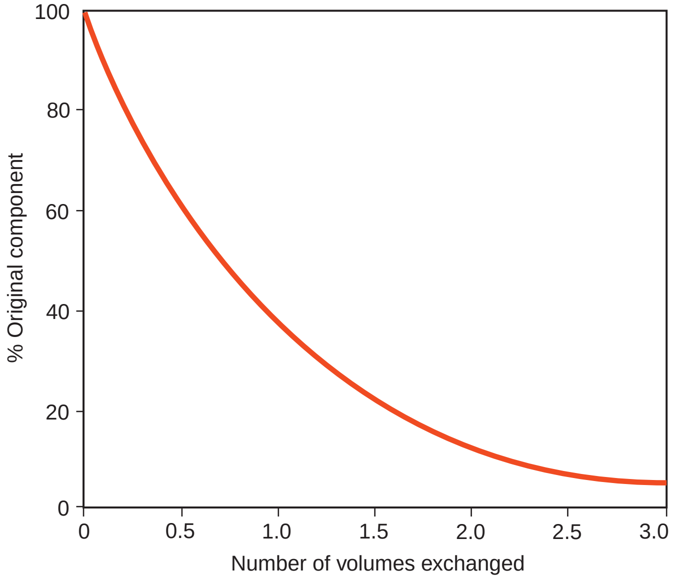


Figure 116.2 RELATIONSHIP BETWEEN VOLUMES REMOVED BY APHERESIS AND PERCENTAGE OF THE TARGET COMPONENT REMAINING. The relation is valid for blood volumes during red blood cell exchange or for plasma volumes during plasmapheresis if the target solute remains primarily within the intravascular compartment.

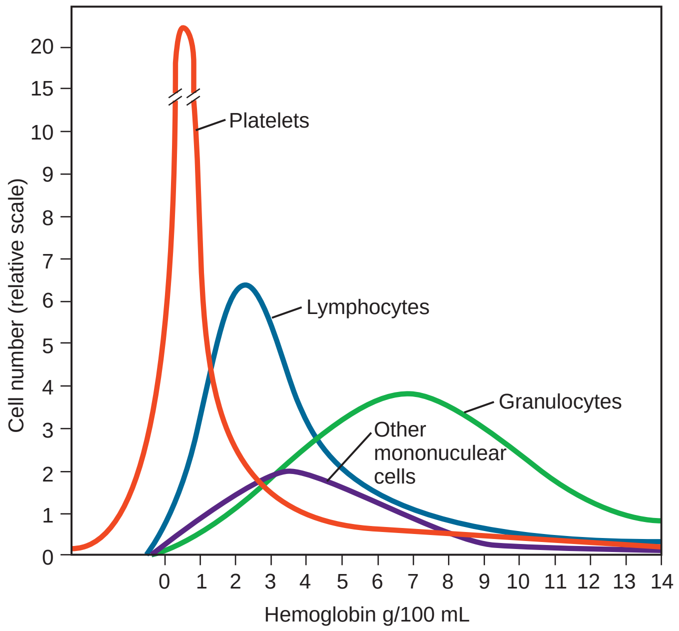

Figure 116.3 SCHEMATIC DISTRIBUTION OF CELLS AT THE COLLECTION PORT OF A CENTRIFUGAL CELL SEPARATOR. The number and percentage of each cell type collected can be varied by adjusting the site of collection along the interface or by changing centrifugal force, blood flow rate, or rate of cell removal.

In large-volume leukapheresis (LVL) procedures, prophylactic intravenous calcium supplementation minimizes the risk of hypocalcemia due to the citrate anticoagulant used.[5]

Because the ideal method for treating disorders mediated by abnormal plasma components is to remove the offending substance selectively, a variety of online filtration and column adsorption techniques have been introduced or proposed. Ligands bound to a column matrix may be relatively nonspecific chemical sorbents, such as charcoal or heparin, or specific ligands, such as monoclonal antibodies and recombinant protein antigens. Two such columns are commercially available: one using staphylococcal protein A, and the other using negatively charged dextran sulfate cellulose beads. Staphylococcal protein A has high affinity for the Fc portion of IgG1, IgG2, and IgG4 and for immune complexes containing these IgG subtypes. The dextran sulfate cellulose columns selectively remove LDL, very-low-density lipoprotein, and lipoprotein, and have proved effective in managing patients with homozygous hypercholesterolemia who have not responded to diet and cholesterol-lowering drug therapy (Fig. 116.4). A similar technique, heparin-induced extracorporeal lipoprotein precipitation, uses low pH and negatively charged heparin to precipitate lipoproteins and remove the precipitate by filtration online (H.E.L.P. Plasmat Futura, Braun Medical). Apheresis technology has also been adapted for extracorporeal phototherapy of patient leukocytes (photopheresis) to treat cutaneous T-cell lymphoma, and to modulate the pathologic immune response in graft-versus-host disease (GVHD), solid organ transplant.

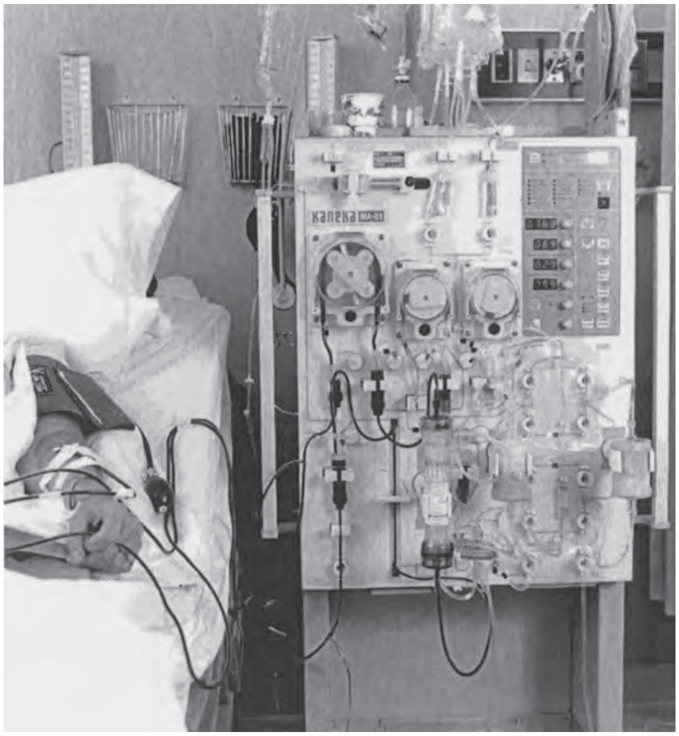

Figure 116.4 TWO-STAGE THERAPEUTIC PLASMAPHERESIS. Plasma is separated from cells by filtration and then passed through parallel adsorption columns to remove low-density lipoproteins from a patient with homozygous familial hypercholesterolemia.

Clinical Consultation With the Apheresis Service

Apheresis services are generally overseen by specialists in Hematology, Nephrology, or Transfusion Medicine; qualified nurses or technicians perform the apheresis procedures. When requesting a course of therapeutic apheresis, the team should specify the indication and urgency of the request as well as the therapeutic endpoint. Defining specific clinical or laboratory endpoints for success, a priori, is important to avoid continuing a fruitless course of apheresis with inherent risks but no clinical benefit. Successful therapeutic apheresis requires reliable vascular access, using either two large, durable peripheral veins or a central dual lumen catheter that is rigid enough to withstand significant flow pressures. The fluid volume removed by therapeutic apheresis must be replaced to prevent marked volume depletion. Some patients, such as small children or pregnant women, may require special technical considerations to appropriately manage volume shifts or minimize intraprocedural anemia. The apheresis schedule should be determined by the patient's condition, the pathologic substance targeted for removal, and the desired clinical and/or laboratory endpoint.

THERAPEUTIC PLASMA EXCHANGE (PLASMAPHERESIS)

Common clinical indications for therapeutic plasma exchange (TPE), frequently referred to as plasmapheresis, are outlined in Table 116.1. Most procedures are performed for treatment of immunologic and hematologic disorders. A course of plasmapheresis generally consists of five to seven exchanges of 1 to 1.5 plasma volumes each, either daily or with an interval of 1 to 2 days between procedures; the course of therapy varies depending on the specific disease indication and rate and duration of the response. Several expert committees have published practice guidelines for using plasmapheresis in a wide variety of disease states.[6] Some of the least controversial indications for plasmapheresis are supported by small series of uncontrolled cases that rely on some objective clinical or laboratory measurement of patient improvement. In recent years, effective biologic and pharmacologic agents such as IVIg have rendered TPE a backup therapy for some indications.

TABLE 116.1 Common Indications for Therapeutic Cytapheresis

Procedure	Indication (ASFA Category)
Red blood cells (RBC) exchange	Acute complications of sickle cell disease (SCD) (e.g., acute stroke [I], acute chest syndrome [II]) SCD, stroke prophylaxis (I) Recurrent vaso-occlusive crises (II) Severe parasitemia, e.g., babesiosis (II), malaria (III)
Erythrocytapheresis	Hemochromatosis, polycythemia vera
Leukapheresis	Symptomatic hyperleukocytosis (II)
Adsorptive cytapheresis	Behçet's disease (II)
Extracorporeal Photopheresis	Cutaneous T-cell lymphoma (I) Acute or chronic graft-versus-host-disease (II)
Cell Therapy Manufacture	Peripheral blood stem cell collection Chimeric antigen receptor T-cell therapy
Thrombocytapheresis	Symptomatic thrombocytosis

Adapted with permission from Schwartz J, Padmanabhan A, Aqui N, et al. Guidelines on the use of therapeutic apheresis in clinical practice—evidence-based approach from the Writing Committee of the American Society for Apheresis: the eighth special issue. *J Clin Apher.* 2019;34:171–354.

REPLACEMENT FLUIDS FOR PLASMA EXCHANGE

The success of therapeutic apheresis procedures seldom depends on the composition of the replacement solution; the major exception is TTP for which plasma is indicated to replace the depleted ADAMTS13 protein. With therapeutic plasmapheresis for most other disorders, the primary function of the replacement solution is to maintain intravascular volume. Additional requirements include restoration of important plasma proteins, maintenance of colloid osmotic pressure, maintenance of electrolyte balance, and preservation of trace elements lost during a prolonged course of plasmapheresis procedures. For most conditions, it is acceptable to perform 1 to 1.5 plasma volume exchanges per procedure. A single plasma volume exchange in an average-sized adult uses approximately 3 L of replacement fluid. In moderately well-nourished patients, homeostatic mechanisms normally obviate the need for precise plasma replacement, and 5% albumin in normal saline or combinations of albumin and crystalloid are usually sufficient. Patients with clinical conditions such as hypotension, hypoalbuminemia, or preexisting coagulopathies should receive solutions prepared specifically to meet their individual requirements. Problems of decreased availability and high cost of albumin have led some centers to develop protocols for alternatives to plasma-derived volume expanders, such as hydroxyethyl starch (HES), for full- or partial-volume replacement with plasma exchange. One center has used a combination of 3% HES and 5% albumin mixture successfully, but patients did experience mild adverse events more frequently than did historical control subjects.[7] Although such solutions are generally well tolerated, extensive replacement with HES in patients undergoing longer courses of plasmapheresis, especially those with impaired renal function, can result in diffuse tissue accumulation of the larger starch molecules (acquired lysosomal storage).

Hematologic Indications for Plasma Exchange

Two of the most common indications for plasmapheresis are treatment of TTP and treatment of clinical syndromes associated with paraproteinemias. Plasma exchange with fresh-frozen plasma (FFP) replacement has been estimated to improve survival rates of patients with TTP from 10% to more than 75%. Whereas plasma infusion is often initiated immediately, TPE is the superior treatment and should be started as soon as it can be arranged.[8] Comprehensive reviews of the clinical and laboratory evaluation and treatment of patients with suspected TTP, including management with plasma exchange therapy, have been published. Treatment usually involves daily single-volume plasma exchange with both frequency and duration of treatment guided by clinical response and continued until the platelet count is above 150,000/μL and lactate dehydrogenase is near normal for 2 to 3 consecutive days. The persistence of schistocytes on the peripheral blood smear does not preclude weaning or discontinuation of treatment. Typically, patients should respond within 2 or 3 days of beginning treatment. In desperately ill and deteriorating patients, escalating the intensity of plasma exchange to twice daily may be necessary.[9] Despite initial reports of improved response rates in certain patients, recent experience suggests that the use of cryoprecipitate-poor plasma may not be more effective than the use of standard FFP as a specific replacement fluid for plasma exchange in patients with TTP. The effectiveness of plasma exchange in this setting may derive from removal of antibody to or replacement of the von Willebrand factor–cleaving zinc metalloprotease, ADAMTS13. However, patients with clinical features of TTP and only moderate ADAMTS13 deficiency or even normal activity may respond to plasma exchange. Refractory TTP may become less common in the era of caplacizumab, a recent front-line therapeutic antibody directed at Von Willebrand Factor (anti-VWF), and novel agents such as recombinant ADAMTS13 which is being evaluated in clinical trials.[10]

TPE is generally not effective in the treatment of other thrombotic microangiopathies (TMA). Plasma exchange for hematopoietic progenitor cell transplant recipients exhibiting clinical features of TMA, now generally referred to as transplant-associated thrombotic microangiopathy (TA-TMA), has proved ineffective and potentially harmful. This syndrome likely differs in pathogenesis from classic TTP in many aspects, including the absence of severe ADAMTS13 deficiency, the spectrum of clinical symptoms, and the lack of evidence of systemic microthrombus formation. Atypical hemolytic uremic syndrome (aHUS), a rare form of thrombotic microangiopathy with high mortality, may be difficult to distinguish clinically from TTP in adults. aHUS results from uncontrolled complement activation, does not respond to plasma therapies, and is instead treated with eculizamab to block the terminal complement complex. Other causes of TMA, such as HUS due to Shiga toxin–producing *Escherichia coli* infection (STEC-HUS) or drug-induced TMA have not been shown to respond to plasma exchange.

Small, uncontrolled studies and extensive clinical experience support the use of plasmapheresis as an adjunctive therapy for patients with paraproteinemia and hyperviscosity syndrome, with some paraproteinemias in the absence of hyperviscosity. Waldenström macroglobulinemia manifests as a lymphoplasmacytic lymphoma with a monoclonal IgM protein in the plasma. Because IgM is a large molecule and resides predominantly in the intravascular space, as little as one apheresis procedure can result in dramatic improvement in symptoms. Recurrence of symptoms and rising plasma viscosity will determine the need and frequency of repeated exchanges. Definitive chemotherapy should be initiated concurrently. Comprehensive reviews describing the rationale and treatment schedules for plasmapheresis in patients with a variety of paraproteinemias, including cryoglobulinemia and Waldenström macroglobulinemia have been published.

In some immune disorders, such as immune thrombocytopenic purpura (ITP) and immune inhibitors to coagulation proteins, plasma exchange may be helpful during a catastrophic event, but in general, benefit of nonselective plasma exchange therapy is not established.

Neurological Disease Indications

Plasmapheresis is effective first- or second-line therapy in selected patients with certain neurologic disorders. Controlled clinical trials of plasmapheresis have demonstrated efficacy in at least two of the polyradiculoneuropathies. In Guillain-Barré syndrome, plasmapheresis should be considered when patients are unable to walk independently or require mechanical ventilation. However, IVIg alone may be equally effective and is more readily available. Periodic plasmapheresis may be necessary in patients with a chronic inflammatory demyelinating neuropathy. Because the long-term prognosis varies, plasmapheresis may be used in conjunction with steroids and IVIg. Rapid deterioration may occur upon discontinuation. Myasthenia gravis (MG) is one of the most common indications for TPE in many hospital settings, particularly in the context of myasthenic crises or refractory MG.[11] Other neurologic disorders characterized by circulating autoantibodies, such as neuromyelitis optica, N-methyl D-aspartate (NMDA)-encephalitis, and Eaton-Lambert syndrome, have also been treated successfully with TPE.

Multiple sclerosis (MS) is a relapsing and progressive disorder with demyelination of the central nervous system white matter. Patients who present with acute fulminant demyelination may benefit from early plasma exchange, particularly when they fail to respond to high-dose corticosteroids.[12] The majority of patients have a relapsing-remitting form of the disease, and plasmapheresis may be of benefit. Unfortunately, for chronic progressive forms of MS, plasma exchange has consistently been shown to be ineffective. Natalizumab (NTZ), an effective treatment for relapsing-remitting MS, may rarely be complicated by progressive multifocal leukoencephalopathy (PML); plasmapheresis has also been attempted to facilitate clearance of NTZ in this context.

Renal Disease Indications for Therapeutic Plasma Exchange

Filtration apheresis devices are commonly used by nephrology services since these devices can be used to perform plasma exchange as well as renal replacement therapy. Plasma exchange is considered first-line adjuvant therapy in patients with anti-glomerular basement membrane disease (Goodpasture syndrome), a disorder characterized by a specific pathogenic autoantibody directed against the renal glomerular and pulmonary alveolar basement membrane. Plasmapheresis has demonstrated similar success in antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides, Plasma exchange has also been used to treat patients with focal segmental glomerulosclerosis, both for primary disease refractory to standard immunosuppressive therapy and for treatment of patients with recurrent disease after renal transplantation.

Plasma exchange appears to be a useful therapeutic option in renal transplant patients with refractory humoral rejection and is now widely used to overcome ABO and HLA incompatibilities between renal transplant patients and their only available donors. Several studies have shown successful reversal of acute humoral rejection mediated by HLA-specific donor antibody using a combination of plasmapheresis and IVIg, which is superior to high dose IVIg alone.[13] A conditioning regimen consisting of pretransplant plasmapheresis, immunosuppressive medications, and low-dose cytomegalovirus immune globulin effectively reduces donor-specific antibody and isoagglutinin titers with and without posttransplant splenectomy and anti-CD20 treatment. The strength of donor-specific antibodies is also important and can be determined by titration, but greater sensitivity and specificity may be obtained using Luminex flow-bead technology. Patients with potent HLA antibodies have increased mean bead fluorescence and were more likely to have acute rejection; however, the introduction of peri-transplantation apheresis reduced acute rejection from 66% to 7%.[14]

Immunoadsorption and Low-Density Lipoprotein Apheresis

Some of the conditions that can be treated with plasma exchange may alternatively be treated by selective adsorption of antibodies from plasma. The staphylococcal protein A–agarose immunoadsorption column (Immunosorba) has been approved by the US Food and Drug Administration (FDA) for removal of autoantibodies to factor VIII or factor IX. A phase III, multicenter, sham-controlled randomized study of staphylococcal protein A column immunoadsorption shows a significant increase in clinical response in adult patients with longstanding rheumatoid arthritis. The Prosorba staphylococcal protein A–silica column was approved in the US for the treatment of ITP but has not been manufactured since 2006.

Evidence that cutaneous lesions and vascular lesions regress in individuals with familial hypercholesterolemia as LDL levels are controlled by plasmapheresis has encouraged the use of apheresis column absorption procedures in patients with homozygous disease and in poorly controlled heterozygous patients. LDL apheresis removes apolipoprotein B–containing lipoproteins from the blood by a variety of techniques, including dextran sulfate cellulose adsorption, immunoadsorption, and heparin-induced extracorporeal precipitation. Short-term safety and efficacy have been demonstrated; however, additional experience will be required to prove long-term benefit for refractory hypercholesterolemia and coronary artery disease for heterozygotes in particular.[15] In 36 homozygous children in two studies, 20% to 22% developed new aortocoronary lesions, or showed progression of existing lesions while on apheresis despite impressive reductions in mean LDL cholesterol.[16,17] Side effects such as malaise, shivering, and pain at the phlebotomy site are common but mild, and the treatments are generally well tolerated. Patients with severe hypertriglyceridemia are at risk of developing acute pancreatitis. Plasma exchange appears to reduce recurrent episodes by an average 67% but requires continuation of medical therapy.

Simple plasma exchange may be used in patients with other inherited metabolic diseases, such as Refsum disease. The frequency of exchange depends primarily on total body burden, rate of synthesis, and plasma concentration of the solute to be removed (Fig. 116.5). Less evidence exists to support a role for repeated treatments in these diseases.

Therapeutic Cytapheresis

Common indications for therapeutic cell removal are listed in Table 116.2. Most of these procedures entail simple apheresis of the patient's peripheral blood with diversion for discarding the affected RBC, white blood cell (WBC), or platelet fraction. Special apheresis technologies have been approved, such as photopheresis devices, which divert a cell fraction that is photochemically treated in the extracorporeal circuit and returned to the patient's circulation, and adsorptive cytapheresis columns, which selectively remove leukocytes by binding to a solid matrix.

Erythrocytapheresis

RBC exchange (erythrocytapheresis with RBC replacement) is used most often to manage or prevent the acute vaso-occlusive complications of sickle cell disease (SCD). Compared to manual exchange transfusion, mechanical cell separators offer the advantages of speed and ease and reduce the risks of rapid blood volume alteration and increased blood viscosity that may occur with simple transfusion. Automated procedures can be performed with all centrifugal instruments, and built-in software programs allow accurate prediction of target hemoglobin (Hb) concentration and percent HbA at the conclusion of the procedure. A single volume exchange will remove about two-thirds of the circulating cells.

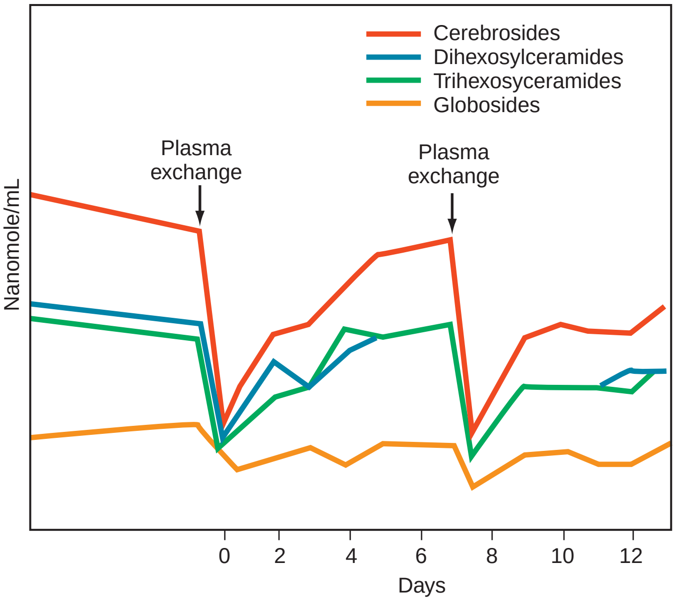

Figure 116.5 PLASMA EXCHANGE TO REMOVE PLASMA NEUTRAL GLYCOLIPIDS IN A PATIENT WITH FABRY DISEASE. The plasma lipid recovery curve appears to be biphasic, reflecting initial reequilibration from tissue stores and subsequent new synthesis of that glycolipid.

TABLE 116.2 **Common Indications for Therapeutic Plasma Exchange (Plasmapheresis)**

Indication (ASFA Category)
Hematologic diseases:
Thrombotic thrombocytopenic purpura (TTP) (I)
Hyperviscosity (I)
Severe cold agglutinin disease (II)
Transplantation:
ABOi liver transplant, desensitization (I)
ABO compatible renal transplant, desensitization (I)*
ABO compatible renal transplant, AMR (I)*
Neurologic diseases:
Myasthenia gravis (I)[a]
Guillain-Barré syndrome (I)[a]
Paraproteinemic demyelinating neuropathy (I)[a]
Renal diseases:
ANCA-associated vasculitis, RPGN (I)
Goodpasture syndrome, anti-GBM with DAH (I)
Recurrent FSGS in kidney transplant (I)[a]
Metabolic diseases:
Homozygous familial hypercholesterolemia (lipoprotein adsorption (I), TPE (II))

[a] Also an indication for immunoabsorption (IA).

The pathophysiology of vaso-occlusive complications in SCD is complex, involving Hb polymerization, change in cell shape, adhesion to endothelial cells, dysregulated nitric oxide homeostasis, and release of free Hb and inflammatory cytokines. The rationale behind exchange transfusion involves improving tissue oxygenation, reducing hemolysis, and preventing microvascular sickling by diluting the patient's abnormal RBCs, simultaneously correcting anemia and favorably altering whole blood viscosity and rheology. No clinical data supports a single optimal level of HbA; however, as few as 30%

of transfused cells markedly decrease blood viscosity. At mixtures of 50% or greater, resistance to membrane filterability approaches normal. In nonemergency situations, such levels can often be achieved with a simple transfusion regimen. For simple and exchange transfusions, raising the level of HbA to between 60% and 70% while lowering the level of HbS to 30% is generally efficacious, although even higher levels of HbA are often used to treat an ongoing crisis. Clinical indications for exchange transfusion in patients with SCD remain controversial, with limited controlled study data available. Simple transfusion has been shown to improve renal concentrating ability and splenic function in young sickle cell patients; exchange transfusion improves exercise tolerance and reverses the periodic oscillations in cutaneous blood flow associated with this disease. Such observations have encouraged the use of exchange transfusion for acute complications of SCD such as acute chest syndrome, priapism, cerebrovascular accident, and hepatic and retinal infarction. Exchange transfusion for sickle cell patients has also been used for prophylaxis during pregnancy and before surgery, although prophylactic transfusion in these settings remains controversial. The only randomized trial of transfusion during pregnancy has shown that prophylactic transfusion sufficient to reduce the incidence of painful crises did not reduce other maternal morbidity or perinatal mortality. The risk of intrauterine growth restriction may be reduced by prophylactic exchange transfusion; however, the study is limited by the retrospective observational nature of the data. In a randomized study of patients with SCD undergoing surgery, a conservative simple transfusion regimen (to increase the Hb level to 10 g/dL) was as effective as an aggressive regimen (to lower the HbS level to <30%) with respect to perioperative complications not related to transfusion. The patients in the aggressive regimen group received twice as many units of blood, had a proportionally increased RBC alloimmunization rate, and had more hemolytic transfusion reactions. A subsequent trial has confirmed that preoperative transfusion is associated with decreased perioperative complications in patients with SCD who are scheduled to undergo low-risk and medium-risk surgeries.[18]

Transfusion prophylaxis is now clearly indicated for children at high risk for stroke. In the absence of primary stroke prevention, approximately 10% of children with sickle cell anemia will have overt stroke and an additional 20% to 35% will have silent cerebral infarction, which can cause cognitive decline and predispose them to additional silent infarcts and overt strokes. Acute stroke in SCD is an indication for RBC exchange, using HbS negative RBC units as the replacement fluid. Red cell units should ideally be antigen-matched for least C, E, and K.[6] A randomized controlled study demonstrated a risk reduction of 90% in the patients who were maintained at levels of 30% or less HbS by simple or exchange transfusion. A second trial addressed whether transfusion could be safely discontinued to avoid the cumulative long-term risks of iron overload and RBC alloimmunization. After 10 months of randomization, half of the patients who discontinued transfusion had developed central nervous system abnormalities, including reversion to abnormal transcranial Doppler findings and a small number of strokes, necessitating early termination of the trial. This result confirms earlier experience and indicates that in this group of children with sickle cell anemia, transfusion therapy should begin before the first event and continue indefinitely. For chronic management, repeated erythrocytapheresis may be preferable to simple transfusion for patients at high risk for stroke who have developed iron overload to levels associated with organ damage.

Exchange transfusion, although relatively safe and convenient, carries all the complications of RBC transfusion. Patients are exposed to a large number of donors and are at a small but increased risk of contracting hepatitis and other blood-borne infections. As many as 33% of all patients develop alloantibodies, and life-threatening delayed hemolytic transfusion reactions have been reported. In addition, an immunohematologic study of multiply transfused sickle cell patients shows that 85% of heavily transfused patients are alloimmunized to human leukocyte antigens (HLAs), platelet-specific antigens, or both. Most centers avoid inducing nonhemolytic transfusion reactions and HLA alloimmunization by using leukocyte-depleted RBCs. Extended RBC phenotyping at diagnosis and provision of phenotypically matched blood, when practical, can reduce the risk of RBC alloimmunization and associated hemolytic transfusion reactions. Isovolemic hemodilution (using saline) prior to standard red cell exchange may be safely employed in patients with SCD undergoing chronic RCE, and reduces the number of RBC units transfused.[19] Despite the removal of RBCs during exchange, most patients remain in positive iron balance, although iron accumulation is slow and chelation is rarely required to prevent transfusional hemosiderosis.

Other indications for RBC exchange are rare. The procedure has been used for patients with overwhelming RBC parasitic infections, such as severe and complicated malaria and babesiosis. Theoretically, automated exchange rapidly decreases the concentration of circulating parasites while improving the rheologic properties of the blood by replacing the infected RBCs. The exchange may also reduce levels of proinflammatory cytokines and may help sustain life until conventional therapy and natural immunity take effect. Although the efficacy of this therapy has not been evaluated by controlled trials, prospective studies and review of published cases suggest the use of erythrocytapheresis for parasitemia greater than 10% to 15% or even less in selected patients such as those with cerebral malaria or pulmonary edema. Case reports document RBC exchange in such diverse conditions as carbon monoxide poisoning and glucose-6-phosphate dehydrogenase (G6PD)–deficient hemolysis.

Automated RBC removal with saline replacement can be performed rapidly and safely in polycythemic subjects. This maneuver should be reserved for polycythemic patients with an urgent clinical indication to lower the hematocrit (e.g., evolving thrombotic stroke) for which standard single-unit manual phlebotomy might be inadvisably slow. Automated double RBC apheresis technology has more recently been used to treat individuals with hereditary hemochromatosis. This procedure removes excess iron more rapidly than manual phlebotomy, and is well received by patients because it lowers the frequency of clinic visits (Fig. 116.6).[20]

Leukapheresis

Therapeutic leukapheresis, also called leukocytapheresis or leukocytoreduction, has been used most successfully to help manage patients with acute leukemia and extremely high WBC numbers, so-called acute hyperleukocytic leukemia (AHL). When the fractional volume of leukocytes (leukocrit) exceeds 20%, blood viscosity increases and leukocytes can interfere with pulmonary and cerebral blood flow and compete with tissue for oxygen in the microcirculation. Investigations of the expression and function of adhesion receptors in leukemic cells, and the role of adhesion molecules in leukocyte-induced acute lung injury in sepsis, suggest that the pathophysiology of leukostasis in AHL may also be related to interactions between leukemic blasts, platelets, and endothelial cells mediated by locally released adhesion molecules. A single-volume leukapheresis procedure generally reduces the WBC count by 20% to 50%, depending on the differing sedimentation characteristics of the specific blast cell population. Hydroxyethyl starch may be used to enhance separation of red cells from blasts, increasing the efficiency of the procedure. Ordinarily, leukapheresis is initiated in a patient with acute myeloid leukemia (AML), or in the accelerated phases of chronic myeloid leukemia (CML) when the blast count exceeds 100,000/mm^3, or when rapidly rising blast counts are higher than 50,000/mm^3, especially when evidence of central nervous system or pulmonary symptoms appears. The threshold for initiation of leukapheresis in patients with acute lymphocytic leukemia (ALL) is generally higher (WBC count >200,000/mm^3). Leukostatic syndromes do not occur when concentrations of well-differentiated lymphocytes exceed even several million/mm^3.

Although leukapheresis is effective in reducing the number of circulating blasts, the evidence for clinical benefit is anecdotal. Case reports and small series describe dramatic improvement of patients with evolving strokes and respiratory insufficiency, but the absence of a randomized controlled trial necessitates reliance on retrospective

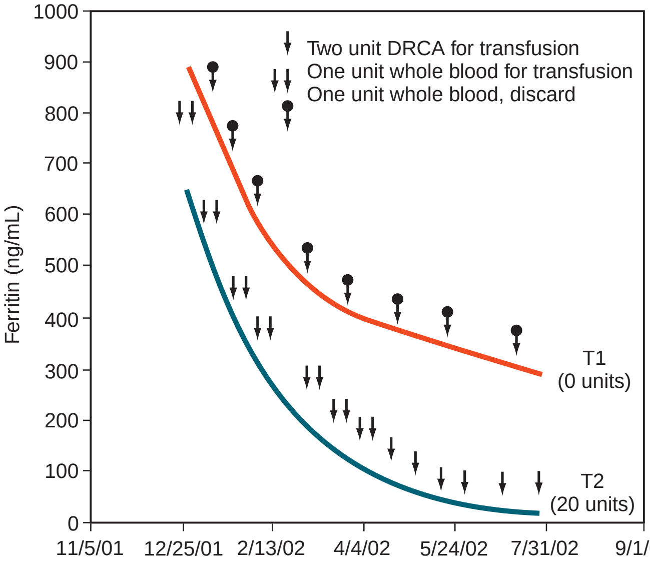

Figure 116.6 ONE TWIN WAS TREATED WITH MANUAL PHLEBOTOMY (T1) AND THE OTHER WITH DOUBLE RED BLOOD CELL APHERESIS (T2). In the same time period, ferritin levels declined more rapidly and to lower levels in the twin treated with double red blood cell apheresis. *DRCA*, Double red blood cell apheresis. *(Unpublished data from Bolan CD, Leitman SF, with permission of the authors.)*

studies. Leukapheresis does not improve the overall survival of patients with AML, and recent reports have not found evidence of a short-term mortality benefit.[21] Because one retrospective cohort study associated leukapheresis with a poorer outcome attributed to a delay in commencing chemotherapy,[22] it seems imprudent to delay other immediate measures for treatment of patients with AHL (infusion of intravenous [IV] fluids, administration of hydroxyurea, and uricosuric medication, urinary alkalization, correction of coagulopathy and thrombocytopenia) while awaiting leukapheresis.

Mechanical cytoreduction for managing other leukemic processes has limited value. Chronic leukapheresis can provide acceptable control of the peripheral WBC count in clinical situations such as pregnancy, when cytotoxic agents may best be avoided. In a small series of gravid patients, leukapheresis in combination with interferon has successfully controlled the disease until therapy with tyrosine kinase inhibitors could be initiated after delivery.[23]

Lymphocyte removal by apheresis has also been used to modify immune responsiveness in patients with autoimmune diseases, and to enhance solid organ allograft survival and reverse solid organ graft rejection. Evidence of clinical efficacy in these situations is sparse. Because leukocytes are a major source of inflammatory cytokines implicated in the pathogenesis of inflammatory bowel diseases (IBD), nonpharmacologic methods for selective leukoreduction have been developed to treat these chronic, relapsing, lifelong disorders. Although IBD respond to a variety of drug regimens, leukapheresis may have a role as a “steroid-sparing” intervention for patients who develop toxicity from long-term steroid use. Cellsorba removes leukocytes by extracorporeal filtration. Granulocyte-monocyte apheresis (Adacolumn) selectively adsorbs cells through columns filled with cellulose beads. Clinical trials using Adacolumn technology have promising results in the treatment of ulcerative colitis (UC), with remission rates in excess of 70% compared with conventional medical therapy, however in a randomized controlled trial the clinical remission rate at 12 months was comparable between the apheresis and control groups.[24] These studies should be interpreted with caution given their reliance on predominantly Japanese patients, which may limit how the results apply to populations with different genetic and environmental factors. The optimum course of therapy is yet to be defined. Recent trials have investigated the safety and efficacy of procedures varying from weekly to a daily basis.

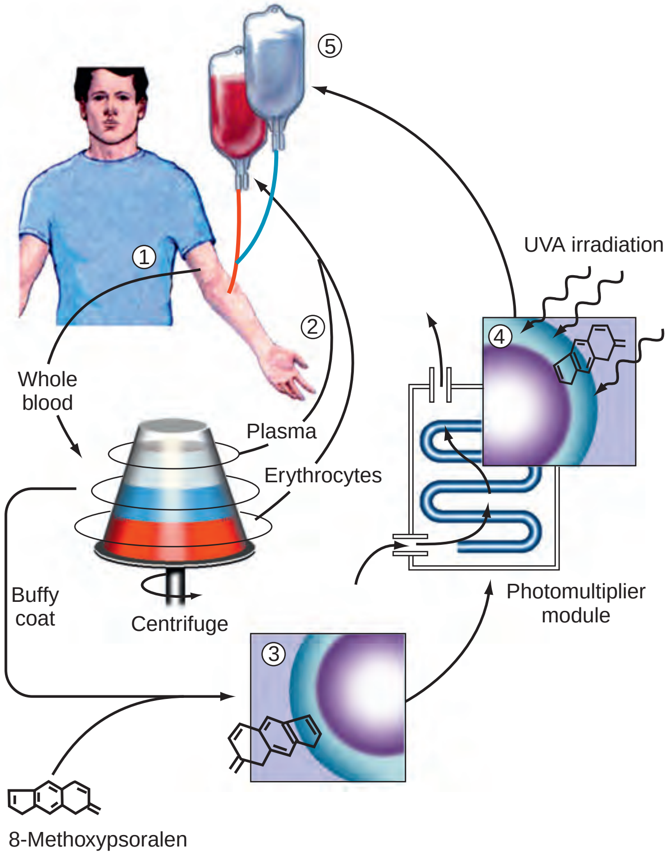

Figure 116.7 OVERVIEW OF A PHOTOPHERESIS PROCEDURE. (1) Vascular access is achieved by placement of a peripheral intravenous line or through a temporary central venous catheter. Whole blood is withdrawn from the patient, mixed with an anticoagulant solution, and pumped to a centrifuge, where it is separated into plasma, red blood cell, and mononuclear cell (buffy coat) fractions by elutriation. (2) After the collection of each mononuclear cell fraction, the uncollected red blood cells and plasma are pumped from the plasma/return bag through a blood filter and returned to the patient. (3) The mononuclear cell fractions are mixed with 8-methoxypsoralen and then (4) pumped through a sterile cassette surrounded by ultraviolet A *(UVA)* bulbs, resulting in a controlled rate and amount of UVA exposure. (5) The treated cell fraction is filtered and returned to the patient.

Extracorporeal Photopheresis

Photopheresis involves automated leukapheresis with extracorporeal photoactivation of WBC using 8-methoxypsoralen (8-MOP), a light-sensitizing agent, and ex vivo ultraviolet A irradiation. The treated leukocyte fraction is then returned to the patient (Fig. 116.7). Delivering the light-sensitizing agent directly to the extracorporeal leukocyte fraction avoids any potential toxicity from oral administration of 8-MOP. The mechanism of action of photopheresis is unproved, but may involve induction of apoptosis of pathogenic T lymphocytes and induction of a dendritic cell-mediated cytotoxic T-cell response. This therapy has minimal toxicity and is highly effective in the treatment of patients with advanced cutaneous T-cell lymphoma. Patients who present with the erythrodermic disease form and circulating malignant cells have the best clinical response. In this context, photopheresis is typically performed once or twice a month. Symptomatic patients with a higher circulating tumor burden benefit from a more intense regimen.[25] More recently, the major use of this technology involves modulation of immune rejection of transplanted organs and management of GVHD after stem cell transplantation in patients who do not respond to standard immunosuppressive therapy. In steroid-refractory acute GVHD, extracorporeal photopheresis (ECP) is thought to enhance regulatory T-cell activity, likely inhibiting the cytotoxic

T cells implicated in the pathogenesis of this condition. Response rates in steroid refractory acute GVHD in pediatric and adult patients range from 52% to 100%. Patients with chronic extensive GVHD have also been treated, with responses observed in approximately two-thirds of the steroid-dependent patients, with cutaneous, oral, and ocular forms of the disease. In the setting of GHVD, patients may require two treatments a week, every 1 to 2 weeks. A response may facilitate a reduction in immunosuppression ("steroid sparing") with continued photopheresis based on results from a randomized phase II trial.[26] In chronic visceral GVHD, where a clear benefit is yet to be established, consideration for treatment should include the logistic challenges of frequent hospital visits and the prolonged need for central venous catheter care and/or transfusion support.

Acute rejection in cardiac transplantation occurs in 25% of recipients in the first year. In 30% to 50% of cases, acute rejection is T-cell mediated. Prospective studies have shown benefit of photopheresis in prevention of rejection. In the case of lung transplant, chronic rejection is manifest as bronchiolitis obliterans syndrome (BOS), presenting as progressive dyspnea and airflow limitation. In a recent prospective nonrandomized study, the rate of decline in lung function stabilized within 6 months of starting ECP therapy compared with rates of FEV_1 (forced expiratory volume in the first second of expiration) which were worsening at baseline. Rates of retransplantation were lower and survival was higher among patients who received ECP treatment. Patients with cystic fibrosis and those with longer interval to BOS development since transplant were less likely to respond to therapy.[27] Of the substantial number of autoimmune disorders for which ECP therapy has been studied, data from small randomized trials have shown benefit in systemic sclerosis (improvement in skin and joint disease severity), and in Crohn's disease (steroid-sparing effect). No significant benefit was demonstrated in type I diabetes or in MS.[28] The acute adverse effects of photopheresis include photosensitivity, low-grade fever, and transient hypotension. Anemia and iron deficiency caused by incomplete reinfusion of RBCs may occur in patients undergoing repeated photopheresis. In patients with inadequate peripheral venous access requiring central venous catheter placement, infection, bleeding, and recurrent clotting are risk factors.

Thrombocytapheresis

Therapeutic plateletpheresis, or thrombocytapheresis, is generally reserved for patients with myeloproliferative disorders and hemorrhage or thrombosis associated with an increase in circulating platelets. Many centers consider using thrombocytapheresis when the patient's peripheral platelet count is greater than $10^6/mm^3$, although no consistent relationship between the level of platelet elevation and the occurrence of symptoms has been found, and no generally accepted assay of platelet dysfunction predicts which patients are at risk. A single cytapheresis procedure can lower the platelet count by 30% to 50%. Thrombocytapheresis can have dramatic effects for selected patients such as those with evolving digital gangrene. Attempts to maintain thrombocythemic patients at normal platelet counts by cytapheresis alone have not been successful; more practical long-term chemotherapy should be instituted concurrently. Because most patients with thrombocytosis do not develop symptoms, including patients with myeloproliferative disorders, prophylactic thrombocytapheresis seems unwarranted regardless of the platelet count. One possible exception involves pregnant patients with essential thrombocythemia who may be at increased risk of first trimester abortion; periodic thrombocytapheresis has been used in a limited series, with weekly procedures necessary to reduce the circulating platelet number until delivery.

Peripheral Blood Hematopoietic Stem and Progenitor Cell Collection

The most common application of apheresis technology for cell therapy indications is the collection of HSPCs from peripheral blood after administration of recombinant hematopoietic growth factor or chemotherapy, or both, to "mobilize" large numbers of HSPCs into the circulation. The collected mononuclear cell fraction contains a subset of progenitor cells that, on infusion, can home to and reconstitute the bone marrow in patients who receive ablative radiation or chemotherapy, or both. Pluripotent HSPCs, and quite possibly primordial hematopoietic stem cells capable of reconstituting the bone marrow and the immune system, have long been known to circulate in the peripheral blood. Numerous studies have confirmed the potential for rapid and durable engraftment of peripheral blood HSPC mobilized into the circulation by hematopoietic growth factors harvested by LVL procedures and subsequently administered to patients with marrow aplasia after high-dose chemotherapy. The concentration of HSPCs in the peripheral blood can be increased by the administration of cytokines, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), and by the administration of chemotherapy. G-CSF for HSPC mobilization is generally administered at a dose of 10 to 16 μg/kg body weight by subcutaneous injection daily for 4 to 5 days prior to apheresis. $CD34^+$ hematopoietic cell counts in the peripheral blood generally rise 20- to 40-fold (from 1 to 3 cells/μL to 40 to 70 cells/μL) after administration of G-CSF alone, and they increase 100- to 1000-fold when chemotherapy rebound is enhanced by administration of G-CSF. Efforts to define optimal collection conditions have been limited by the lack of a standardized assay; however, time and level of increase of donor peripheral blood WBC and $CD34^+$ cell counts after administration of mobilizing agents have proved to be useful indicators. Despite ongoing challenges with interlaboratory standardization, flow cytometric analysis of cells labeled with a fluorochrome-conjugated CD34 antibody are used for "real-time" decision making about the timing and adequacy of PB HSPC collections. Several prestimulation donor variables are important. Increasing age, white ethnicity, and female gender are associated with significantly lower post–G-CSF $CD34^+$ cell counts, which would favor younger males as donors when high cell doses are required.[29]

Several clinical scale devices for $CD34^+$ cell enrichment of leukapheresis collections by immunoabsorption or immunomagnetic techniques are available. This "positive selection" of $CD34^+$ hematopoietic cells also results in reduced numbers of cells that do not express the CD34 antigen, such as T lymphocytes. T-cell–reduced products may confer a lower risk of GVHD, and the ability to produce apheresis products enriched for $CD34^+$ cells facilitates graft manipulations for experimental cell therapies such as ex vivo expansion of $CD34^+$ cells. However, some studies suggest a higher incidence of engraftment failure and possibly delayed immune reconstitution in certain patient populations when transplants are performed with highly purified, CD34-selected T-cell–depleted products.

Over the last decade, PB HSPCs have surpassed bone marrow HSPCs as the predominant graft source in the clinical setting for various hematopoietic stem cell transplants. PB HSPCs are the graft of choice in 99% of conditions where autologous transplants are indicated. For allogeneic transplants, especially those using stem cells from matched unrelated donors or in pediatric transplants, bone marrow stem cells still remain the popular graft source. PB HSPC transplants result in higher rates of clinically significant chronic GVHD in these situations. Table 116.3 provides a summary of comparisons of bone marrow versus PB HSPCs in different types of allogeneic stem cell transplants.

From a donor perspective, the discomfort and inconvenience of multiple-day cytokine administration may be a significant deterrent. Most donors experience some degree of malaise and bone pain, and some donors require hospitalization for more serious adverse reactions to G-CSF administration. However, a large prospective trial of the National Marrow Donor Program found intensity and duration of pain in the peri-collection period was similar for persons undergoing HSPC collection by apheresis (during G-CSF administration before apheresis) and following bone marrow harvest procedure in bone marrow HSPC donors). Furthermore, 3% of bone marrow donors reported ongoing low-grade site pain after 6 months of completing the procedure, whereas recovery was complete for PB HSPC donors by this time. Risk factors for worse toxicities, including older

TABLE 116.3 Bone Marrow Versus Cytokine Stimulated Peripheral Blood Stem Cells as Graft Source of Choice for Hematopoietic Stem Cell Transplantation

Disease Category	Recipient Age Group	Type of Donor	Preferred Graft Source (Unstimulated BM vs. Cytokine Stimulated PB HSPC)
Nonmalignant (e.g., severe aplastic anemia)	All ages	Sibling	BM HSPCs
Malignant	Pediatric	Sibling	BM HSPCs
Malignant	Adult	Sibling	PB or BM HSPCs (PB HSPCs preferred in high-risk leukemia)
Malignant	Adult	Matched unrelated donor	PB or BM HSPCs (PB HSPCs preferred if high graft failure risk; BM HSPCs if high cGVHD risk, prior immunosuppression)

BM, Bone marrow; *cGVHD*, chronic graft-versus-host disease; *HSPC*, hematopoietic stem and progenitor cell; *PB*, peripheral blood.

age, female gender, and obesity were similar among bone marrow and PB HSPC donors.[30] While concerns remain regarding the hypothetic long-term effects of exposure of healthy donors to growth factors, another recent prospective study with more than 20,000 donor-years of follow-up, showed no evidence of increased risk for cancer, autoimmune illness, and stroke in donors receiving G-CSF.[31] Splenic enlargement occurs commonly, and several instances of splenic rupture have been reported. Citrate toxicity is a common complication of HSPC collections; although usually mild and transient, it may be severe and even life-threatening in some individuals (see previous section). Venous access requires large-bore multilumen catheters, and these appear particularly susceptible to clotting, especially when patients receive recombinant cytokine stimulation. Hemorrhage, especially in thrombocytopenic patients, is another potentially severe complication of central venous catheter placement.

Some patients who have received multiple prior cycles of chemotherapy and a small proportion of normal healthy donors, referred to as "poor mobilizers," fail to respond adequately to mobilization regimens. In this circumstance, Plerixafor, a reversible CXCR4 antagonist that can block the adhesion of HSPCs to the bone marrow stroma can enhance collections by releasing these cells into the circulation. In a randomized controlled trial, the combination of G-CSF and a single dose of Plerixafor resulted in a significantly higher proportion of patients with non-Hodgkin lymphoma achieving their target cell dose in fewer apheresis days.[32] Similar success is achieved with multiple myeloma patients achieving a 4.8-fold increase peripheral blood CD34 cell count compared with 1.7-fold with G-CSF alone. Emerging evidence indicates that Plerixafor may be administered "just-in-time" to rescue collections for patients who mobilize poorly with G-CSF alone. While the optimum circumstances and timing for administration have not yet been determined, some guidelines recommend addition of Plerixafor for circulating $CD34^+$ cell counts less than 20×10^6/L on two consecutive days accompanied by increasing WBCs.

A novel indication for HSPC apheresis is to facilitate autologous gene therapy for patients with hemoglobinopathies. SCD and thalassemia are inherited hemoglobinopathies characterized by mutations the β-globin gene, causing production of abnormal hemoglobin (HbS) or inadequate globin chains and ineffective erythropoiesis. Allogeneic HSPC transplantation may be curative but identifying a related acceptable donor may be challenging. A novel approach is underway in clinical trials, utilizing transplantation of genetically modified autologous HSPC with either repair of the β-globin mutation or targeting genetic loci associated with reactivation of endogenous γ-globin expression. Bone marrow may be a source of HSPC for such approaches. However, recent trials in patients with SCD have shown that HSPC derived from mobilization and apheresis are superior to marrow due to higher HSPC yields and faster hematologic recovery compared to bone marrow, and a better cellular phenotype.[33] G-CSF mobilization with or without plerixafor results in safe and adequate $CD34^+$cell mobilization in patients with β-thalassemia; however, G-CSF is contraindicated in patients with SCD due to severe life-threatening complications in this population. Mobilization, using plerixafor as a single agent HSPC apheresis in participants with SCD, was impacted by known clinical factors that hinder stem cell mobilization in healthy adults such as age and bone marrow reserve as measured by pre-apheresis CD34/μL, white blood cell (WBC), and platelet counts. Disease severity as measured by hospitalization frequency in the preceding year and number of medications required to treat chronic pain, were also predictive of a lower total $CD34^+$ yield.

MONONUCLEAR CELL COLLECTION FOR CELLULAR IMMUNOTHERAPIES

Blood cell separators developed for hemapheresis are used to collect peripheral blood cells for cellular therapy. Donor leukocytes obtained from leukapheresis procedures may be used for donor lymphocyte infusion (DLI) or subject to further processing for immunotherapy. DLIs from allogeneic HSPC transplant donors are used to treat graft failure or disease relapse in recipients with hematologic malignancies. Collection of autologous lymphocytes from patients has been increasing with the expansion of the field of novel cellular therapies such as CAR-T cells. CAR-T-cell therapies are most commonly used to treat hematologic malignancies, primarily B-cell acute lymphoblastic leukemia or lymphoma; other indications include multiple myeloma and prostate cancer. Compared to healthy donors, patients who have previously undergone stem cell transplantation, or received lymphodepleting chemotherapy may be anemic and have significantly reduced total WBC and lymphocyte counts. This poses a challenge in collecting sufficient T cells to allow for CAR-T manufacture. Some CAR-T-cell manufacturers have recommended minimum lymphocyte counts in trials, such as an absolute lymphocyte count (ALC) >500/μL or $CD3^+$ >150/μL for the manufacture of tisagenlecleucel. In lymphopenic patients, the WBC, ALC or $CD3^+$ count prior to apheresis may be used to estimate the number of blood volumes needed to process to obtain the desired number of lymphocytes.

PEDIATRIC HEMAPHERESIS

Pediatric therapeutic apheresis accounts for about 10% of all apheresis procedures. The indications for apheresis in children are limited by a lack of clinical trial data. Therefore, the evidence for therapy in many diseases is extrapolated from trials in adults despite differing patient physiology and an age-dependent presentation and natural history of the disease. For example, hemolytic uremic syndrome is more common in children and responds to supportive care; at the other end of the spectrum of this disease, TTP is more common in adults and necessitates plasma exchange.

The majority of apheresis procedures in children are erythrocytapheresis for patients with SCD and autologous HSPC collections after chemotherapy rebound (e.g., for neuroblastoma). Increasingly, mononuclear cell collections for CAR-T cell manufacture to treat acute leukemia is becoming more frequent in the pediatric population with high-dose chemotherapy. ECP is used for GVHD; and both ECP and TPE have been used as adjunct treatment modalities for solid organ rejection, with sparse data thus far. In adults, TPE is shown to be efficacious in acute and chronic demyelinating neuropathies and in severe refractory MG. TPE may also benefit children with rare neurologic disorders; pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) and Sydenham chorea (SC) are autoimmune neuropsychiatric disorders that occur rarely after infection with group A β-hemolytic streptococcal infections. Circulating immune factors may contribute to the pathogenesis of these diseases. These conditions respond to IVIg and plasmapheresis. In a small, randomized study, 50% of patients with SC also responded to plasmapheresis, and although superior to corticosteroids, treatment with IVIg had the best response, with 72% of patients having a reduction in symptoms of chorea. Small pediatric studies have demonstrated benefit of TPE specifically in recurrent focal segmental glomerulosclerosis, especially when it occurs post renal transplantation. It has been attempted with marginal success in severe refractory vasculitides such as Henoch-Schönlein purpura, Kawasaki disease, and ANCA-associated vasculitides.[34]

Technical Aspects

The mechanics of apheresis were developed for adults and therefore designed for their larger circulating blood volume. Therefore, depending on the size of the child, modifications to the apheresis procedure may be necessary. Central venous catheters are required in most circumstances because the caliber of peripheral venous access is too small to permit adequate blood flow. In pediatric apheresis, maintenance of isovolemia is essential to prevent circulatory compromise, particularly in an acutely ill child who may have some degree of cardiac or renal impairment. The beginning and end of the apheresis procedure involves negative and positive intravascular fluid shifts, respectively. Typically, volume shifts have negligible impact on an adult's circulation but can represent a substantial proportion of the total blood volume (TBV) of an infant. The volume of the patient's blood required to fill the apheresis circuit at the start of the procedure is the extracorporeal volume (ECV). Symptomatic hypovolemia becomes increasingly likely as ECV exceeds 15% of TBV. An ECV of 400 mL represents 8% of the TBV of a 70-kg patient but may be as much as 35% for a 15-kg infant. Modification of the apheresis procedure is necessary for safe management in infants and small children.

In adults, the apheresis circuit is primed with saline, which is then diverted to the collection or waste bag. One option permits the return of saline prime to the patient, which may be useful for larger children. For children who weigh less than 25 kg, priming the circuit with RBCs is often necessary to prevent intravascular volume depletion and severe anemia. Upon completion, fluids remaining in the apheresis circuit, typically returned to the adult patient, are not returned in pediatrics to avoid a positive fluid shift causing fluid overload.

COMPLICATIONS OF THERAPEUTIC APHERESIS

Automated apheresis is a minimal-risk procedure for normal healthy blood and plasma donors. The current generation of blood cell separators is remarkably reliable and equipped with sensitive detection and alarm systems to alert the operator to potential problems. Nevertheless, serious morbidity and rare deaths have been associated with therapeutic procedures. In most reports, deaths are related to either complications associated with the use of central venous access catheters, or to cardiac and respiratory problems in patients who were critically ill before apheresis; in the latter, the contributory role of the apheresis procedure is often questionable. The most common adverse effects of therapeutic apheresis are citrate-induced hypocalcemia, allergic reactions (usually to donor plasma or other blood components), vasovagal reactions, and hypovolemia. If transient paresthesia and mild vasovagal events are excluded, approximately 5% of all therapeutic apheresis procedures have medical complications. The frequency of adverse reactions is influenced by the experience of the operator and the nature of the patient population being treated. Expected and predictable effects of therapeutic apheresis include alterations in laboratory parameters caused by removal and dilution by replacement fluids. A 5% to 15% decrease in Hb and hematocrit, a 20% to 30% decrease in platelet count, and mild transient increase in leukocyte count are commonly observed. Significantly, but transiently abnormal coagulation test results are often observed (recovery generally occurs within 48 hours after a single-volume exchange procedure), as well as clinically insignificant decreased levels of other plasma proteins after serial plasma exchange procedures. The most common adverse effect of both donor and therapeutic apheresis procedures is symptomatic hypocalcemia caused by infusion of calcium-chelating citrate ions in the anticoagulant, and if used as replacement fluid, anticoagulated donor plasma. Hypocalcemia is usually manifested by mild perioral, acral paresthesia, or both, requiring no intervention other than slowing the reinfusion rate. The benefit of oral calcium supplements in this setting is questionable, although the practice is widespread. Hyperventilation may exacerbate the symptoms of hypocalcemia. More severe citrate toxicity is uncommon; signs may range from involuntary carpopedal spasm, nausea, and vomiting to frank tetany with spasm in other muscle groups, including life-threatening laryngospasm and grand mal seizure. Severe toxicity is most commonly experienced by small patients, particularly women, when the blood flow rate is rapid and the procedure is prolonged beyond a few hours. Symptoms correlate inversely with the level of ionized calcium. Extremely low concentrations of ionized calcium are encountered routinely in therapeutic procedures that process more than 15 L of blood. Acute severe hypocalcemia leading to fatal cardiac arrhythmia has been reported in patients who have undergone apheresis. Controlled infusions of 10% calcium gluconate or calcium chloride are effective in the prevention and management of these complications. Because metabolism of citrate occurs predominantly in the liver and kidney, patients with conditions affecting these organs are at increased risk for severe citrate reactions. Studies of TPE procedures and of HSPC donations performed with and without calcium gluconate or calcium chloride infusion show the effectiveness of continuous calcium infusion for the prevention of mild to moderate citrate toxicity (Fig. 116.8). A study of plateletpheresis donors demonstrated by

Controlled study of citrate effects and response to i.v. calcium administration during allogeneic peripheral blood progenitor cell donation. Transfusion. 2002;42:935, used by permission.)*

PATIENT MANAGEMENT ISSUES FOR THERAPEUTIC APHERESIS

Important issues to consider when preparing a patient for therapeutic apheresis, for monitoring the patient during the procedure, and for managing the patient after removal from the apheresis device include:

Preparation

- Volume considerations: Calculate volume to be processed or exchanged; order replacement solutions; assess patient volume status. A blood prime may be necessary for children who weigh less than 25 kg.
- Vascular access: Assess need for apheresis line placement. Note that not all large catheters are suitable for apheresis procedures.
- Medications: Evaluate impact of medications (Coumadin, platelet inhibitory agents, angiotensin-converting enzyme inhibitors) and indications to suspend certain medications. Albumin-bound medications may be depleted by apheresis.
- Cell counts: Patient may require transfusion for preprocedure anemia or thrombocytopenia.
- Electrolytes: Assess risks for citrate toxicity; order calcium replacement solutions if indicated.

Procedure

- Volume considerations: Monitor replacement fluids (saline-to-albumin ratio). Rapid infusion of refrigerated solutions may cause hypothermia.
- Vascular access: Observe for impaired, intermittent, or obstructed flow. Kinked tubing can result in hemolysis.
- Medications: Limitations on blood or citrate flow rate caused by symptomatic citrate-induced hypocalcemia may necessitate addition of anticoagulant to the final apheresis product or inclusion of heparin in the anticoagulant regimen.
- Cell counts: Consider the impact of very high or low cell counts on device settings and procedure efficiency.
- Electrolytes: Continually monitor for adverse citrate effects; bolus or continuous intravenous calcium administration may be required.

Postprocedure Management

- Volume considerations: Review net volume balance and consider additional infusion or administration of diuretic if needed.
- Vascular access: The decision to remove the apheresis catheter should include the possibility of additional apheresis or procedures; monitor for complications associated with maintenance or removal of venous catheter.
- Medications: Determine when to restart medications; consider the impact of transiently reduced coagulation factor levels.
- Cell counts: The patient may require transfusion for postprocedure thrombocytopenia; monitor cumulative red blood cell and platelet loss after repeated procedures.
- Electrolytes: Assess for imbalance postprocedure with attention to ionized calcium and magnesium as indicated by symptoms.

changes in alkaline phosphatase, osteocalcin, parathyroid hormone, and 1,25-dihydroxyvitamin D levels, suggesting the potential for long-term effects on bone metabolism in these donors. Magnesium, another divalent cation, is also bound by citrate. Despite decreases in serum ionized magnesium levels to 39% below baseline, clinical effects are not typically observed even during LVL procedures. The most severe allergic complications occur when plasma is used as the replacement solution, and this risk increases with repeated exposure. Allergic reactions to ethylene oxide, an agent used in the sterilization of plastic disposable equipment, have been reported. IV diphenhydramine is usually effective in managing allergic reactions; premedication with steroids and precautions against anaphylaxis may be necessary for sensitized individuals. Atypical (hypotension and flushing) and anaphylactic reactions have been reported in patients receiving angiotensin-converting enzyme inhibitors undergoing different apheresis procedures, including immunoadsorption with staphylococcal protein A columns. These medications should be discontinued for at least 24 hours before LVL or plasma exchange. Unlike donors undergoing apheresis for donation of RBCs, platelets, or plasma, donors undergoing apheresis for collection of therapeutic granulocytes are stimulated with steroids and G-CSF before donation. The well-known association of long-term steroid treatment and posterior subcapsular cataracts is likely irrelevant in the context of short-term steroid stimulation for donor granulocyte mobilization. However, an increased number posterior subcapsular cataracts has been detected in three separate studies including an analysis of 100 granulocyte donors compared with age-matched plateletpheresis donors, suggesting that granulocyte donors may be at increased risk for cataract formation. Repeated steroid stimulation for granulocyte collection warrants regular ophthalmologic examination and close follow up.[35] Serious complications indirectly associated with therapeutic apheresis include adverse consequences of large-needle vascular access; namely, retroperitoneal or pericardial hemorrhage, phlebotomy site aneurysm formation, pneumo- or hemothorax, thrombosis, nerve damage, and infection. A retrospective review of 381 TPE procedures at one institution reported an approximately 1% incidence of severe complications, all of them related to central venous catheters (see box on Patient Management Issues for Therapeutic Apheresis).

CONCLUSIONS AND FUTURE DIRECTIONS

Apheresis is now most commonly performed to obtain blood components for transfusion or plasma for fractionation from healthy donors. As a therapeutic intervention, apheresis is used to treat neurologic, renal, and hematologic disorders where removal of a pathogenic antibody or cell population is considered helpful as a primary or temporizing measure. While the field of apheresis science is shifting to an evidence-based approach, therapeutic apheresis is still utilized in the absence of much supporting evidence of efficacy. Effective pharmacologic agents have supplanted therapeutic apheresis for many disease indications. Increasingly, apheresis is being used to collect starting material for hematopoietic stem cell transplantation, cellular immunotherapies, and potentially curative gene therapies. Medical oversight and optimization of these autologous donor procedures is likely to play a key role in the future of apheresis in the years to come.

CHAPTER 117

TRANSFUSION REACTIONS TO BLOOD AND HEMATOPOIETIC STEM CELL THERAPY PRODUCTS

Martin R. Schipperus and Johanna C. Wiersum-Osselton

A *transfusion reaction* can be defined broadly as any adverse event that occurs in association with the infusion of a blood or cell therapy product. Transfusion reactions are classified by how close to transfusion they occur (timing), how much morbidity is caused (severity), how strong the causal association of the event is with transfusion (imputability), as well as by its fit to a (standardized) definition of a transfusion reaction type. Every year, approximately 40 fatalities definitely, probably, or possibly attributable to transfusion are reported to the US Food and Drugs Administration (FDA). Similar rates of transfusion-associated fatalities are found in the International Haemovigilance Network's surveillance database ISTARE (0.26 cases per 100,000 units transfused; 2006–2016) and emerge from data on fatalities as reported to the European Commission annually by member states (0.26 per 100,000 units in 2017).

Stopping the transfusion at the first sign of a transfusion reaction, usually fever, is critical for preventing severe sequelae. Although the great majority of febrile reactions to blood transfusion are not caused by blood incompatibility, it is impossible to exclude this possibility at the bedside. All transfusion reactions need to be reported to the blood transfusion laboratory to exclude incompatibility.

It is important to recognize that many transfusion reactions can mimic pathology unrelated to transfusion. The differential diagnosis of any untoward clinical event should always consider adverse sequelae of transfusion, even when transfusion occurred weeks earlier. This chapter reviews the presentation, mechanisms, and management of transfusion reactions (Table 117.1). Approximate risks of selected transfusion reactions are shown in Fig. 117.1.

TABLE 117.1 Types of Acute Transfusion Reactions

Reaction Type	Presenting Signs and Symptoms
Acute hemolytic	Fever, chills, dyspnea, vomiting, hypotension, tachycardia, infusion site pain, back pain, hemoglobinuria, hemoglobinemia, indirect hyperbilirubinemia, renal failure, disseminated intravascular coagulation
Febrile reaction	Fever, chills, rigors
Allergic	Urticaria, pruritus, flushing, angioedema, dyspnea, bronchospasm, stridor, hypotension, tachycardia, abdominal cramping
Hypervolemic	Dyspnea, tachycardia, hypertension, headache, jugular venous distention
Septic	Fever, chills, hypotension, tachycardia, vomiting
Transfusion-related acute lung injury	Dyspnea, hypoxemia, fever, hypotension

HEMOLYTIC TRANSFUSION REACTIONS

Hemolytic transfusion reactions are caused by the immune-mediated clearance of transfused incompatible red blood cells (RBCs). Immune-mediated hemolysis can be classified clinically according to the timing of the reaction (acute or delayed), as caused by either ABO or non-ABO incompatibility, and mechanistically by the site of hemolysis: intravascular with terminal complement activation or extravascular with phagocytosis in liver and spleen (Table 117.2).

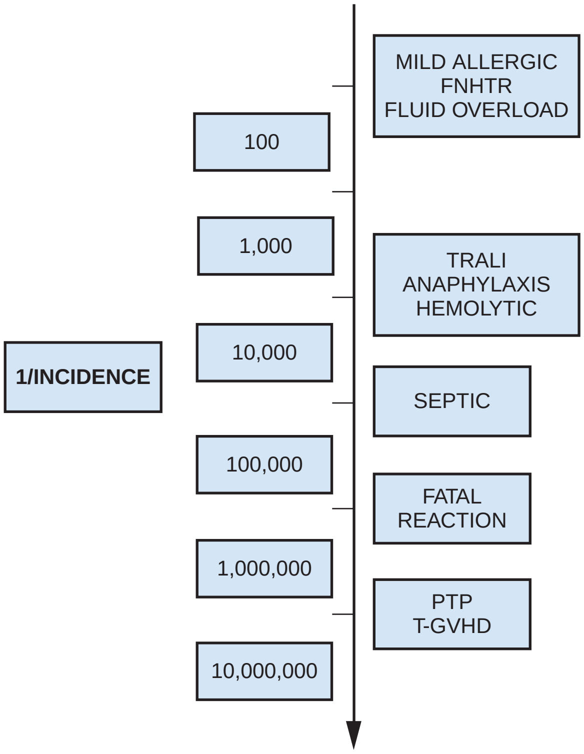

Figure 117.1 APPROXIMATE RISK OF VARIOUS TRANSFUSION COMPLICATIONS. *FNHTR*, Febrile nonhemolytic transfusion reaction; *PTP*, posttransfusion purpura; *t-GVHD*, transfusion-associated graft-versus-host disease; *TRALI*, transfusion-related acute lung injury.

TABLE 117.2 Hemolytic Transfusion Reactions: Serologic Presentation

Type	Antibody Detectable Initially	Primary Antibody Type	Degree of Complement Binding	Example
Acute intravascular	Yes	IgM	Full (C1–9)	ABO system
Acute extravascular	Yes	IgG	None/partial	Rh system
Delayed intravascular	No	IgG	Full (C1–9)	Kidd system
Delayed extravascular	No	IgG	None/partial	Duffy system

Although hemolytic transfusion reactions are mechanistically considered immune-mediated in most cases, thermal, osmotic, infectious, and mechanical destruction of RBCs also can lead to acute hemolysis.

ACUTE INTRAVASCULAR HEMOLYTIC TRANSFUSION REACTIONS

Pathophysiology

Acute hemolytic reactions are those that occur during or within 24 hours, typically after incompatible RBCs are transfused into a patient with preexisting antibodies. A reaction caused by a naturally occurring antibody against ABO-incompatible RBC is the prototypical example of an acute, intravascular hemolytic transfusion reaction. ABO antibodies are naturally occurring immunoglobulin IgM and less commonly IgG antibodies to foreign A and B blood group antigens. IgM antibodies efficiently fix and activate complement after binding to ABO-incompatible RBCs. The formation of excessive terminal membrane attack complexes consisting of complement components C5 through C9 creates multiple pores in the transfused RBC membranes, resulting in a clinically significant acute intravascular hemolytic transfusion reaction. Such a reaction could occur, for example, after transfusion of A RBCs into an O recipient who has significant amounts of circulating anti-A (see box on Acute Hemolytic Transfusion Reaction). The excess cell-free hemoglobin that is generated supersaturates the binding capacity of plasma albumin, haptoglobin, and hemopexin and manifests by hemoglobinemia and hemoglobinuria. Free heme induces renal vasoconstriction through nitric oxide scavenging. This may eventually result in acute tubular necrosis and renal failure. In IgM-mediated ABO-incompatible transfusion reactions, activation of the complement cascade generates anaphylatoxins C3a and C5a, leading to capillary leak, hypotension, and phagocyte and mast cell activation. Furthermore, the deposition of C3b on the RBC membrane increases extravascular hemolysis.

In addition to complement components, cytokines also play a role in the clinical syndrome of hemolysis and fever. For example, interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α have pyrogenic activity; IL-8 is a neutrophil chemotactic and activating factor. These four cytokines have been generated in various in vitro models of intravascular hemolysis and IgG-mediated RBC incompatibility. TNF-α induces tissue factor expression on endothelium while decreasing thrombomodulin, which contributes to disseminated intravascular coagulation (DIC). TNF-α also promotes endothelin production, promoting renal vasoconstriction. The clinical variability of hemolytic transfusion reactions is explained in part by the relative balance of cytokine production in the transfusion recipient. Factors that increase the circulating levels of proinflammatory cytokines and chemokines often result in more severe reactions. Factors that determine the severity of hemolysis include the antibody titer, antibody avidity, antibody subtype, antigen density on the RBC membrane, and volume and infusion rate of incompatible blood. Patient factors also play an important role. Transfusing as little as 30 mL of incompatible RBC concentrate can be fatal, and there is a direct relationship between increasing volumes of incompatible blood transfused and mortality. Conversely, there may be no reaction at all in an elderly or immune-compromised patient, or in the setting of massive transfusion.

Acute hemolytic reactions can also occur with incompatible plasma transfusion. Because of limited platelet inventories, platelet components with incompatible plasma are frequently transfused, for example, a group O platelet concentrate (with anti-A) transfused to a group A recipient. This plasma incompatibility (i.e., minor incompatibility) can occasionally result in acute ABO-incompatibility hemolytic reactions.

ACUTE HEMOLYTIC TRANSFUSION REACTION

A 15-year-old blood group O male with sickle cell disease presents for routine simple transfusion for primary prevention of stroke. He has no history of red blood cell (RBC) alloimmunization and his pretransfusion compatibility testing shows a negative screen for RBC alloantibodies. Seven minutes into the transfusion, the patient reports not feeling well. He quickly develops chills, abdominal pain, flank pain, and pain at the infusion site. The transfusion is stopped. Vital signs show a 15 mm Hg drop in systolic blood pressure from baseline value, pulse of 130, and a temperature increase from afebrile pretransfusion to 38.9°C. Gross hematuria is seen in a subsequent urine sample. Reinspection of the blood unit shows that it is group A and labeled with the name of the child receiving blood in the infusion chair next to him. The patient is transferred to the emergency room where he is evaluated for renal failure and diffuse intravascular coagulation (DIC).

Clinical Manifestations and Laboratory Testing

An acute intravascular hemolytic transfusion reaction is a medical emergency. Initial clinical symptoms can include fever and chills, shortness of breath, chest pain, dizziness, reddish urine, back or flank pain, hypotension, and oliguria. Some patients report feeling anxiety or pain or warmth ascending from the site of infusion. RBC transfusions must be stopped and the patient evaluated clinically and by laboratory testing if fever develops (≥2°C increase in temperature). The transfused incompatible RBCs undergo complement-mediated lysis, producing hemoglobinemia and hemoglobinuria. Cardinal signs of an acute intravascular hemolytic transfusion reaction are the presence of red plasma (hemoglobinemia) and red/dark urine (hemoglobinuria). Acute transfusion reactions can quickly progress to shock and acute renal failure. Many patients, curiously even anephric patients, often complain of lower back pain. It is speculated that this symptom is caused by ischemic muscle pain or vasospasm rather than by kidney pain from developing renal failure.

When an acute hemolytic transfusion is suspected, the transfusion should be stopped immediately and clerical checks performed to check ABO and Rh compatibility and verify that the correct unit is being transfused to the intended recipient. If it is confirmed that the transfusion was ABO-incompatible, it is important to investigate where an error occurred. If there has been a mix-up of samples or units, could a second patient be receiving an incorrect unit? There may be a systemic error that could put other patients at risk.

Laboratory findings confirming hemolysis include hemoglobinuria, hemoglobinemia, and a haptoglobin level that is low to undetectable. During the hemolytic episode, the bilirubin (especially indirect bilirubin) usually increases only modestly (2 to 3 mg/dL) if the patient has normal liver function. Because of the lysis of RBCs, levels of lactate dehydrogenase (LDH) may rise markedly. The direct antiglobulin test (DAT) becomes positive in an immune hemolytic reaction (if tested before all the incompatible RBCs are destroyed). Preparation of an antibody eluate is often necessary to identify the presence of an offending IgG antibody. Elution is a procedure that

WORKUP OF AN ACUTE INTRAVASCULAR HEMOLYTIC TRANSFUSION REACTION

If an acute transfusion reaction occurs:

1. Stop blood component infusion immediately.
2. Maintain intravenous access with a suitable crystalloid or colloid solution.
3. Maintain an adequate airway.
4. Monitor/maintain blood pressure and heart rate. Monitor renal status (blood urea nitrogen, creatinine, volume status).
5. Give a diuretic or institute fluid diuresis, or both.
6. Evidence is lacking for the use of corticosteroids and this is therefore not recommended.
7. Obtain blood and urine studies for the transfusion reaction workup.
8. Transfusion laboratory workup of suspected transfusion reaction:
    - Check paperwork and identification to ensure the correct blood component was transfused to the correct patient.
    - Observe plasma for hemoglobinemia.
    - Perform direct antiglobulin test.
    - Repeat compatibility testing (crossmatch).
    - Repeat other serologic testing as needed (ABO, Rh).
    - Analyze urine for hemoglobinuria.
9. Monitor coagulation status (prothrombin time, activated partial thromboplastin time, fibrinogen).
10. Monitor for signs of hemolysis (lactate dehydrogenase, bilirubin-total/direct, haptoglobin).

chemically separates the bound antibody from the RBCs and concentrates it so that it may be identified.

Initial therapy consists of immediately stopping the transfusion, administering intravenous fluids, cardiorespiratory support, and ensuring a brisk diuresis. Increasing renal blood flow is the best way to prevent acute oliguric renal failure. Usually, 0.9% NaCl is infused to maintain a urine output of 100 mL/h for approximately 24 hours. Diuresis can be achieved with loop diuretics or mannitol, but this is not evidence based. The mechanisms responsible for the beneficial effect of increased renal blood flow likely include increased clearance of free hemoglobin and a return of more physiologic control of renal vasodilation. Creatinine and blood urea nitrogen (BUN) should be monitored; dialysis may be necessary for the treatment of oliguric acute renal failure. Support of blood pressure and respiration may require the use of vasopressors, bronchodilators, or intubation. DIC can occur in severe cases. The prothrombin time, activated partial thromboplastin time, and fibrinogen level should be monitored (see box on Workup of an Acute Intravascular Hemolytic Transfusion Reaction). If the patient shows no signs of cardiovascular instability and if hemostatic and renal function are unchanged at least 24 hours after the incompatible transfusion, the episode can be considered to be over, with serious sequelae unlikely.

ACUTE EXTRAVASCULAR HEMOLYTIC TRANSFUSION REACTIONS

In an extravascular hemolytic transfusion reaction, complement is either not fixed at all or is fixed only to C3b. In either situation, because of the nature of the antigen-antibody reaction, complement activation with fixation of the C5b-9 complex does not occur. This presentation is commonly associated with Rh antibodies but can be seen with any number of non-ABO antigen-antibody complexes. The presence of IgG bound to the RBCs or C3b fixation results in an extravascular reaction because the antibody-coated cells are cleared by IgG receptors in the spleen or C3b receptors in the liver. In these circumstances, RBC lysis does not occur in the intravascular space. Because of the lack of generation of C3a or C5a, an extravascular hemolytic transfusion reaction does not usually present as a clinical emergency. It is characterized by a positive DAT caused by recipient RBC alloantibodies binding to the incompatible circulating donor RBCs. Moreover, an increase in indirect bilirubin, an increase in LDH, a decrease in hematocrit, a decrease in haptoglobin, and an increase in colorless urine urobilinogen can occur, but hemoglobinuria and hemoglobinemia are rarely present. The patient typically remains clinically stable. Renal failure, shock, and hemostatic abnormalities, such as DIC, are rarely seen unless the amount of incompatible blood infused is excessive. However, patients often have a low-grade fever.

When an extravascular hemolytic transfusion reaction is suspected, the diagnostic test of choice is a DAT with an eluate. The eluate is performed to identify the antibody coating the RBCs. The positive DAT result reflects the patient's antibody (or antibodies) coating the incompatible donor RBCs. Because this is not an autoantibody, the patient's own RBCs are not involved in the reaction.

Typically an acute extravascular hemolytic transfusion reaction requires no special therapeutic intervention if the volume of incompatible blood transfused is relatively low. The patient characteristically recovers in a few days as the incompatible donor RBCs are cleared from the circulation. If the volume of incompatible blood transfused was high, hemolysis can quickly lead to anemia through destruction of the transfused RBCs. Communication with the transfusion laboratory is key to identifying how many units of incompatible units were transfused.

Extravascular acute reactions may occur if the patient's preexisting alloantibody was missed by the blood transfusion laboratory during the antibody screening process. If a wrongly labeled sample was used, if the unit of blood was labeled for the wrong patient, or if the unit was transfused in the wrong patient, an extravascular acute reaction is a possible consequence.

Hyperhemolysis

Hyperhemolysis is a specific type of acute intravascular hemolysis of (autologous) bystander RBCs that do not express the antigen to which an immune-mediated hemolysis is directed.

Hyperhemolysis occurs primarily with transfusion in the setting of sickle cell disease and is also reported to occur in acute malarial infection, passenger lymphocyte syndrome, paroxysmal nocturnal hemoglobinuria, and select cases of autoimmune hemolytic anemia. Since hyperhemolysis is frequently associated with sickle cell disease, Petz and colleagues proposed the term *sickle cell hemolytic transfusion reaction syndrome* to describe the constellation of hemolysis, sickle cell pain crisis, reticulocytopenia, severe anemia, RBC transfusion leading to accelerated hemolysis, and lack of a clear serologic reason for hemolysis. Hyperhemolysis is frequently fatal because transfusion may exacerbate hemolysis and the primary treatment for severe anemia (RBC transfusion) makes anemia worse. Recognition of this syndrome is therefore critical because treatment should shift from transfusion to administering erythropoietin, glucocorticoids, intravenous immunoglobulin (IVIG), and rituximab, which have been used successfully in case series.

DELAYED HEMOLYTIC REACTIONS

The pathogenesis of delayed hemolytic transfusion reactions (DHTR) is similar to that described for acute hemolytic reactions. However, in DHTRs, the patient develops hemolysis 3 to 10 days after the transfusion as an anamnestic antibody response to a blood antigen previously known to the patient's immune system through transfusion, pregnancy, or hematopoietic stem cell transplantation (HSCT). Delayed hemolytic reactions are slower in onset than acute reactions and are less likely to present as a clinical emergency. Hemoglobinuria and hemoglobinemia can occur but are less pronounced than with an acute intravascular reaction. This is probably because of the gradual increase in antibodies, as well as the fact that most DHTRs are caused by antibodies not efficient at activating complement. The need for intervention is much less likely than with an acute hemolytic transfusion reaction, but hematologic and renal monitoring are prudent.

DHTRs are the most common presentation of transfusion-associated immune hemolysis. DHTRs often involve the Rh system. Patients present with a fever, a falling hemoglobin level, and the development of a positive DAT with an eluate demonstrating a new RBC alloantibody. Because these reactions are typically mild in nature, they are usually addressed with supportive care only. In patients with sickle cell disease, DHTRs can precipitate vaso-occlusive crises, autoantibody production, or hyperhemolysis. It is essential to take a transfusion history in people with sickle cell disease who present with new complications.

One final note regarding the serologic evaluation of a transfusion reaction: posttransfusion testing may be complicated and difficult to interpret because of the possibility of autoantibodies or the involvement of medications. In such circumstances, testing on the pretransfusion specimen is often helpful. In cases of more complex evaluations, consultation with an expert in immunohematology is recommended to detect and identify new alloantibodies in the patient's plasma, which may be responsible for a hemolytic transfusion reaction.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

A febrile nonhemolytic transfusion reaction (FNHTR) is suspected if there is a rise in temperature of ≥1°C (with or without rigors/chills) during or within 4 hours following transfusion without any other cause such as hemolytic transfusion reaction, bacterial contamination, or underlying condition, with normalization within 24 hours after the transfusion. Cases with a rise in temperature ≥1°C (<2°C), without other relevant symptoms or signs are considered to be a mild (nonhemolytic) febrile reaction. The most serious FNHTR, with fever (≥39°C oral or equivalent and a change of ≥2°C from pretransfusion value) and chills/rigors, should always be adequately investigated. FNHTR could be present in the absence of fever (if chills or rigors without fever).

Evidence supports two mechanisms of FNHTR: antileukocyte antibodies and cytokines. Cytotoxic or agglutinating antibodies having human leukocyte antigen (HLA) specificity, neutrophil specificity, or platelet specificity may be present in the recipient's plasma and react against antigens present on transfused donor lymphocytes, granulocytes, or platelets. Conversely, donor plasma may contain the offending antibody that can react with the corresponding cellular antigens in the recipient's blood. Leukocyte-derived cytokines IL-8, IL-1β, and IL-6 accumulate in platelet products in particular and induce fever. IL-1, through prostaglandin PGE_2 synthesis, is thought to stimulate the thermoregulatory center of the hypothalamus to produce fever. Other mediators such as macrophage inflammatory proteins (e.g., MIP-1) may also participate in the febrile response, but this reaction is not mediated through prostaglandin synthesis. CD154 (CD40 ligand) derived from platelets is also involved in febrile reactions by inducing cyclooxygenase-2 and PGE_2. Leukoreduction should theoretically lead to a reduction of leukocyte-derived cytokines in the blood product but appears to be less effective at preventing FNHTRs to platelets than to red cell components because of platelet-derived biologic response modifiers. Nevertheless, studies show that the generation of cytokines during storage is directly proportional to the leukocyte count of the unit and the duration of storage. Implementation of prestorage leukoreduction has been shown to reduce the incidence of FNHTR.

The frequency of febrile reactions for a nonleukoreduced unit has been estimated to be 6.8 per 100 units RBCs transfused and 2.2 per 100 units platelet transfused. With the advent of prestorage leukoreduction, these risks have been decreased to about 0.09 to 1.1 per 100 units RBCs transfused and 0.04 to 1.56 per 100 platelet units transfused. Reactions are most commonly seen in recipients who have been exposed to multiple white cell or platelet antigens. Patients with bone marrow failure (primary or chemotherapy-induced) are at risk as a result of frequent transfusions, as are multiparous women who may have received multiple exposures during pregnancy and childbirth. These groups of patients can form multiple HLA-, granulocyte-, or platelet-specific antibodies that will react with white cells or platelets upon subsequent exposure.

The workup of a febrile reaction must be undertaken promptly because fever may also be the first sign of other, more severe reactions, including acute hemolysis or sepsis. A hemolytic transfusion reaction may be ruled out by reconfirming the ABO and Rh type of the patient and the donor unit, performing antiglobulin crossmatching to confirm patient-donor compatibility, evaluating the results of the pretransfusion and posttransfusion DATs, evaluating the serum for hemolysis, and rechecking the accuracy of paperwork. The posttransfusion DAT should yield negative findings because FNHTRs do not involve RBC alloantibodies.

As laboratory testing is being completed, the workup should include bedside patient evaluation. Fever and chills may be attributable to drugs or underlying diseases, or they may be associated with infection or inflammation. Neutropenic fever often complicates the clinical picture in patients undergoing intensive, myelosuppressive chemotherapy, a population of patients likely to receive repeated RBC or platelet transfusions. Blood cultures of the patient and the blood product should be considered, especially if the patient has high fever or shows signs of sepsis (see later text and box for a more in-depth discussion of suspected posttransfusion bacteremia/sepsis). Routinely, blood cultures and microbiological cultures of the blood product are ordered in order to differentiate an FNHTR from posttransfusion bacteremia that may be a reaction to a bacterially contaminated blood product or be associated with an infection in the patient. It is not routine to investigate for (or identify the specificities of) HLA, platelet, or granulocyte antibodies that could cause FNHTRs. Accordingly, the diagnosis of an FNHTR is usually made as a diagnosis of exclusion without isolating an identifiable antibody.

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions complicate up to 3% of all transfusions. The allergic manifestations occur on a spectrum of severity. They can include flushing, urticaria, pruritus, angioedema, hypotension, bronchospasm, stridor, abdominal pain, and emesis. An anaphylactic reaction is a systemic immediate hypersensitivity reaction, which can be defined as allergic signs and symptoms in skin/mucosa and at least one other organ system (cardiovascular, respiratory, gastrointestinal). Shock is the most ominous manifestation of anaphylaxis, but bronchospasm and upper airway angioedema are more common manifestations (see box titled A Severe Allergic Transfusion Reaction).

Allergic transfusion reactions manifest similarly to other IgE-mediated, immediate hypersensitivity reactions. Mast cells are the primary allergic effector cells for immediate hypersensitivity reactions; basophils may play a secondary role. Mast cells and basophils can be activated by cross-linking cell surface high-affinity IgE receptors or via IgE-independent mechanisms, such as complement receptor binding by C5a. Upon activation, histamine is released immediately, as it is stored preformed in granules. Platelet-activating factor, a

A SEVERE ALLERGIC TRANSFUSION REACTION

A 34-year-old man with thrombotic thrombocytopenic purpura has been receiving daily 60 mg prednisone and daily plasmapheresis for 8 days without complication. Halfway through the ninth procedure, he rapidly develops severe angioedema of the face and tongue, stridor, wheezing, diffuse flushing, and urticaria. Tachycardia develops with stable blood pressure. The urgent intervention team is called and the patient is administered oxygen, epinephrine intramuscularly, albuterol nebulizer, diphenhydramine, ranitidine, and methylprednisolone. Symptoms resolve over the next 12 h without the need for escalated respiratory support. The patient receives another 3 weeks of plasma exchanges with two sporadic minor allergic reactions (focal urticaria and pruritus only).

potent arachidonic acid derivative that mediates anaphylactic shock, is produced rapidly, along with a variety of other eicosanoids, for example, leukotrienes.

Generally, allergic transfusion reactions are diagnosed clinically. The incidence is associated with the plasma content of the product, so it is thought that a plasma protein is responsible for many reactions.

Following a severe anaphylactic reaction, if relevant, an allergic mechanism can be confirmed by measuring a rise in serum tryptase. Further investigations may be performed to establish the trigger although most anaphylactic transfusion reactions remain idiopathic. Examples of IgG or IgE with specificity to IgA, haptoglobin, and C4 have been described. Case reports describe moderate or severe anaphylactic reactions in patients who are severely IgA deficient (<0.05 mg/dL) and have anti-IgA antibodies. However, the generalizability of this mechanism is low. Most cases of fatal anaphylaxis are not related to IgA deficiency, and most severely IgA-deficient people tolerate transfusions well. Thus, patients with incidental IgA deficiency may receive routine blood components, and IgA/anti-IgA testing should be reserved for patients with anaphylactic reactions. Quantitative haptoglobin can also be considered as a screening test particularly in Asian populations, as rare cases of haptoglobin deficiency are associated with anaphylactic reactions.

There are several reports of allergic transfusion reactions to autologous transfusion, suggesting that a storage lesion or conceivably a substance from the bag may be responsible for some reactions. Passively transferred IgE combined with allergen exposure in the recipient is a mechanism that has been described for food and antibiotic-mediated allergic transfusion reactions, but these are uncommon.

Over 90% of allergic transfusion reactions occur during infusion. A severe allergic (anaphylactic) transfusion reaction is a medical emergency and should be treated promptly as described in the box above. However, the majority of allergic transfusion reactions are milder. When allergic symptoms develop, transfusion should be stopped and the patient given an antihistamine like clemastine. The transfusion may resume, but only if the symptoms resolve and the patient feels well. A mild allergic reaction (urticaria and pruritus) during a blood transfusion usually does not progress to a more severe anaphylactic reaction after infusion of additional blood from the same unit. The severity of allergic transfusion reactions is not directly related to volume infused or infusion rate.

Even among the minority of patients with recurrent reactions, most transfusions are tolerated well. Patients who have had more than one mild allergic reaction may continue to receive routine units. Washed RBCs or plasma-reduced platelets can be used to prevent severe, recurrent reactions; however, washing cellular products compromises component quality. Washing RBCs leads to accelerated in vitro hemolysis, while washing platelets increases platelet activation and lowers posttransfusion platelet count increments. Platelets produced with platelet additive solution as storage medium and pooled, solvent detergent plasma are relatively new products that have been shown to be associated with a lower incidence of allergic transfusion reactions. Leukocyte depletion or the use of microaggregate filters does not reduce allergic transfusion reactions.

There is no evidence that antihistamine premedication prevents allergic transfusion reactions, although antihistamines do mitigate symptoms when they occur. Studies in healthy volunteers support a synergistic role for treating histamine-mediated reactions with both H1 and H2 receptor antagonists, for example, diphenhydramine and ranitidine, respectively. Corticosteroids, provided in advance of a transfusion, also may be useful in patients with serious recurrent reactions.

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) is an important pulmonary complication of blood transfusion in which inflammatory pulmonary edema develops within 6 hours of transfusion. Symptoms of TRALI range from mild dyspnea to severe noncardiogenic pulmonary edema, with features that include dyspnea, oxygen desaturation, respiratory failure, chills, fever, and hypotension. Most patients require oxygen support, and many require mechanical ventilation. TRALI is one of the leading causes of transfusion-related death reported to hemovigilance systems—the others being transfusion-associated circulatory overload (TACO), acute hemolytic transfusion reactions, or transfusion-transmitted bacterial infections (TTBIs), depending on the setting.

It is postulated that TRALI consists of a “two-hit” event, the first “hit” being an underlying clinical condition that leads to the sequestration and priming of neutrophils in the lung tissue. In some cases of TRALI, referred to as immune TRALI, the second hit consists of the transfusion of blood products containing anti-HLA or anti-HNA (human neutrophil antigen) antibodies to cognate antigens in the patient that activate the neutrophils in the lung parenchyma, leading to edema. Complement and monocyte activation with the aggregation of white blood cells also may occur when leukoagglutinins present in the recipient react with leukocytes contained in the infused donor blood. As a result of the leukocyte antigen-antibody reaction, the activated leukocytes express adhesive molecules on their surface (CD11/CD18), which then permit leukocytes to attach to pulmonary endothelial cells and migrate to the interstitial space between the pulmonary capillaries and the alveolar epithelium. Once in the interstitial space, neutrophils degranulate and through enzymatic digestion produce capillary dehiscence that results in fluid filling the alveolar sacs. Pulmonary leukostasis with pulmonary edema thus occurs as a result of microvascular occlusion and capillary leakage. Complement-activated granulocytes also produce oxygen radicals that damage pulmonary endothelial cells, resulting in a further increase in pulmonary vascular permeability and additional passage of fluid into alveolar spaces.

Other cases of TRALI are non-immune, and in these cases, the second hit is believed to arise from the presence in stored blood components of biological response modifiers such as bioactive lipids and soluble mediators, such as CD40L. Rodent model systems for TRALI have also been described, and some of these models suggest a role for platelets in TRALI. Further research is necessary to elucidate the different mechanisms leading to this syndrome, which may be a final common pathway from a variety of initiating insults.

In a typical case of TRALI, the patient becomes acutely dyspneic or shows decreased oxygen saturation during or up to 6 hours after transfusion. Physical examination reveals findings (crackles) of pulmonary oedema but without raised jugular venous pressure or elevation in cardiopulmonary pressures. The chest radiograph typically shows a pulmonary edema pattern with bilateral infiltrates but should not show vascular congestion. Copious amounts of fluid are produced in the lungs, and there may be frothy sputum. The alveolar oedema in TRALI is an inflammatory exudate as opposed to the transudate of cardiogenic oedema. TRALI usually follows infusion of relatively small volumes of blood, whereas fluid overload more often arises from larger volume transfusions. TRALI can be hard to distinguish from fluid overload without central cardiovascular pressure measurements. When a patient shows signs of increasing respiratory effort, the infusion should be immediately stopped, as it should be with all other reactions. Treatment of patients with TRALI is supportive (Table 117.3).

Because of the role of antileukocyte antibodies in triggering TRALI, these cases are reported to the blood establishment to allow for testing to identify donors with antileukocyte antibodies to the cognate antigens in the affected patient (the donor is then “implicated”) and their permanent deferral from blood donation. It should however be noted that anti-HLA antibodies found in such testing may match a frequent HLA type, and the finding of antibodies could have been coincidental. Prevention of TRALI has focused on providing blood components without anti-HLA. Antileukocyte antibodies are most likely present in blood donors who are (multi)parous women so many blood services now supply plasma for transfusion from male donors without a history of blood transfusion, and in some cases also from female donors who have tested negative for anti-HLA antibodies. Using male-only plasma started in the 2000s and led to a reduction in reported TRALI cases by about a third.

TABLE 117.3 Transfusion-Related Acute Lung Injury

Onset	Within 6h of the start of transfusion, usually within 2h
Frequency	1:10,000 transfusions
Signs and symptoms	Hypoxemia, fever, hypotension, tachypnea, dyspnea, diffuse pulmonary edema
Pathogenesis	HLA/granulocyte-specific antibodies (usually of donor origin) reacting with recipient leukocytes or directly with endothelium. Lysophosphatidylcholines that accumulate during component storage can activate neutrophils in an antibody-independent manner.
Diagnosis	Chest radiograph; blood gases; post/pretransfusion NT-BNP ratio <1.5; blood for HLA or antineutrophil antibodies
Differential diagnosis	Fluid overload; septic transfusion; anaphylaxis; unrelated acute lung injury
Treatment	Stop transfusion. Provide respiratory support (administer O_2, intubation may be needed), support blood pressure, no evidence supporting glucocorticoids or diuretics

HLA, Human leukocyte antigen; NT-*BNP*, N-terminal brain-natriuretic peptide.

The original TRALI case definition was developed in a consensus conference (Toronto, 2004). Subsequent research, both on this transfusion complication and on the acute respiratory distress syndrome (ARDS) has led a group of clinically based researchers to propose a redefinition incorporating newer insights on TRALI and ARDS (2019). Notably, there is an updated Berlin ARDS definition (2012) in which the former term of acute lung injury has been dropped outside the transfusion setting in favor of mild ARDS. For cases following transfusion, the group recommends classification as TRALI type I or type II based on the absence or presence of recognized risk factors for ARDS. In Type II TRALI, even if (mild) ARDS was already present, the patient can still be diagnosed with (Type II) TRALI if their respiratory status was stable for 12 hours before transfusion. Cases may also be classified as TRALI/TACO if it is impossible to distinguish between the two types of complication or both types of complication are present simultaneously. Validation of the revised TRALI definition for use in clinical and hemovigilance settings is awaited.

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD

TACO results from hydrostatic transudate accumulation in the lungs and should be considered in patients who, during or within 6 to 12 hours after a blood infusion, develop dyspnea, jugular venous distension, tachycardia, or other signs of congestive heart failure and fluid overload. An increase in blood pressure and widened pulse pressure may be observed.

Hemovigilance systems find that TACO is the leading cause of reported transfusion-related serious morbidity and mortality and particularly occurs in association with RBC transfusion. It is likely that symptoms of incipient circulatory overload in transfused patients often respond to extra diuretic therapy and go unreported.

TACO Risk Factors and TACO Prevention

Acute expansion of a (non-bleeding) patient's intravascular volume may exceed the capacity of the cardiovascular and renal systems to compensate, resulting in fluid overload. Risk factors for the development of TACO are compromised cardiopulmonary status, significant renal impairment, small body weight—infants, the elderly—or clinically significant preexisting positive fluid balance. If a patient is judged to be at increased risk, preventive measures should be considered (see box on TACO Preventive Measures).

TACO PREVENTIVE MEASURES

Transfuse a Single Unit and Review

State speed of infusion on the blood order (prescription), e.g., 1 mL/kg/h in patients at increased risk and otherwise 2–3 mL/kg/h in non-bleeding patients.

Consider prophylactic loop diuretic before start of transfusion e.g., 20–40 mg furosemide IV.

If TACO is suspected, the transfusion should be stopped and the patient's blood volume reduced by diuretics and oxygen or additional support given as indicated. Careful monitoring of a transfused patient's vital signs during transfusion may allow treatment to be instated before the patient progresses to full-blown TACO with respiratory compromise.

TACO, Transfusion-associated circulatory overload.

The initial stages of TACO may be difficult to distinguish from hemolytic transfusion reaction, FNHTR, allergic reaction, or TRALI. The absence of hemoglobinuria and hemoglobinemia and the absence of a positive posttransfusion DAT result distinguish the reaction from one caused by immune hemolysis. The presence of fever and chills is more typical in septic transfusion reactions, hemolysis, or febrile transfusion reactions; but new fever has been reported in up to a third of TACO cases. Radiographic imaging may support the diagnosis by showing a widened cardiac silhouette and vascular pedicle and changes of congestive pulmonary oedema; however, it can be challenging to distinguish between TACO and TRALI or infectious infiltrates. Blood levels of brain-type natriuretic peptide (BNP) or its precursor N-terminal pro-brain-natriuretic peptide (NT-proBNP), which are increased in left atrial strain, may aid in the diagnosis if NT-proBNP is at least 50% higher posttransfusion than pretransfusion.

POSTTRANSFUSION INFECTIONS AND BACTERIAL CONTAMINATION

In past decades, notably in the 1980s, public concern and scandal have focused on the occurrence of transfusion-transmitted infections (TTIs). Since that period, testing strategies, processing methods, and pathogen reduction technologies have contributed to large reductions of the infectious hazards. Nevertheless, it is important to remain aware of the possibility of bacterial, viral, or other TTI. A report can be classified as a TTI if:

- The recipient(s) had evidence of infection post transfusion with blood components, and there was no evidence of infection prior to transfusion, and no evidence of an alternative source of infection is found, and, either:
- At least one component received by the infected recipient(s) was donated by a donor who had evidence of the same transmissible infection or:
- At least one component received by the infected recipient was shown to contain the agent of infection

Posttransfusion Bacteremia/Sepsis

A posttransfusion bacteremia/sepsis is defined by clinical symptoms of bacteremia/sepsis arising during, directly after, or some time subsequent to a blood transfusion, with a relevant positive patient blood culture result; a causal link to a transfused blood component may or may not be confirmed through a finding of the same bacterial species in the component or other material from the donor.

When no signs or symptoms of a bacteremia or sepsis are present in the patient, but a positive culture of the blood product is found, this could be reported as bacterial contamination of a blood component as

SUSPECTED POSTTRANSFUSION BACTEREMIA/SEPSIS

A 29-year-old woman in week 38 of pregnancy received a unit of apheresis platelets prophylactically in a clinic for a chronic bone marrow failure syndrome of unclear etiology. During the infusion, she developed flank pain and coughing. The transfusion was stopped and the patient was admitted. She became febrile to 39.3°C 90 min after transfusion. Blood cultures from the patient and bag grew *Staphylococcus aureus* within 12 h.

Blood transfusion is common in people with bone marrow failure, either primary or secondary to intensive myelosuppressive chemotherapy. These patients are also often neutropenic and may have central venous catheters or take immunosuppressive medications. Despite these underlying risk factors, transfusion should always be considered a potential source of bacteremia. If there is a suspicion that blood components may be the source of infection it is critical to inform the blood establishment in order for other components manufactured from the same collection(s) to be blocked or recalled for investigation. Yomtovian and colleagues prospectively cultured all platelets issued from a large hospital blood bank and found contaminated units similar to other reported rates (~1:2000). When they relied on passive reporting of septic reactions from clinicians, the incidence fell to zero, only to increase back to baseline once active culturing of platelets resumed.

collected by some hemovigilance systems. Bacterial contamination is defined by the presence of relevant numbers of bacteria in a (remnant of) blood component or in the bacterial screen bottle of a platelet component, or in material from the same donation, demonstrated in the approved way with laboratory techniques, preferably including typing of the bacterial strain or strains.

Note: This commonly occurs in the setting of the routine bacterial screening of platelet concentrates, which are distributed "negative to date."

Posttransfusion bacteremia/sepsis resulting from a bacterially contaminated component—this can be termed transfusion-transmitted bacterial infection (TTBI)—is relatively rare. Only one red cell–related death per year has been reported from approximately 13,898,000 units of red cells or whole blood that are transfused in the United States. *Yersinia enterocolitica* is the most common bacterial contaminant of PRBC; other pathogens include *Serratia marcescens*, *Pseudomonas aeruginosa*, and *Enterobacter* species. Incidence is directly related to the length of storage.

Platelet-related sepsis is more common than sepsis following RBC transfusion. The risk of symptomatic bacterial sepsis per pool or apheresis unit of platelets is in the order of 1:100.000. (See box on Suspected Posttransfusion Bacteremia/Sepsis.)

HYPOTENSIVE TRANSFUSION REACTION

While a drop in blood pressure may occur in patients with a range of transfusion reactions such as acute hemolysis, a severe allergic reaction or TRALI, in some cases an isolated, clinically relevant drop in systolic or diastolic blood pressure, arises during or up to 1 hour after administration of a blood component. These reactions are categorized as hypotensive transfusion reactions, with the ISBT definition and US Biovigilance protocols stating that in adults there should be a drop of 30 mmHg or more and a systolic pressure of 80 mmHg or lower. Typically, the patient responds to stopping the transfusion and supportive therapy with intravenous fluid (saline).

When hypotensive reactions were first described, an association was noted with an infusion of components leukoreduced using a particular type of bedside leukocyte filter. Moreover, reactions have been noted to occur in patients taking angiotensin-converting enzyme inhibitors. A role of bradykinin in the infused blood component has been postulated, but a definitive mechanism for hypotensive reactions in association with prestorage leukoreduced components has not been postulated. Hypotensive transfusion reaction remains a diagnosis of exclusion. If a patient receiving a blood transfusion shows an abrupt drop in blood pressure (even before the changes reach levels specified in the definitions), it is essential to respond promptly by stopping the transfusion, evaluating the patient clinically, and performing laboratory and any further investigations as clinically indicated.

POSTTRANSFUSION PURPURA

Posttransfusion purpura (PTP) is a rare and self-limiting thrombocytopenia occurring 5 to 10 days posttransfusion in patients lacking a specific platelet antigen, usually HPA-1a (also called PLA1, GPIIIa, CD61). These patients may have a history of prior transfusions or pregnancies. Indeed, about 85% of cases occur in women. After re-exposure to transfusion, patients can develop potent antibodies against the platelet-specific antigen that they are lacking but which is present on donor platelets. These platelet antibodies often have a high titer and can fix complement. As a result, the transfused platelets and the patient's own platelets are also destroyed through the adsorption of the antigen or immune complexes on their own platelets. A concurrent autoimmune process may also involve the destruction of the recipient's own platelets, as shown in one case report of a positive antibody against the patient's own platelets. The thrombocytopenia can be marked with a platelet count falling below 10,000/μL. The onset is sudden, although this complication is self-limiting, and usually resolves in 2 weeks. This severe thrombocytopenia can help distinguish PTP from heparin-induced thrombocytopenia, which can also be considered in the differential diagnosis when thrombocytopenia develops 5 to 10 days after combined heparin exposure and blood transfusion, for example, major surgery.

In patients who already have thrombocytopenia, diagnosing PTP can be difficult, especially when the patient already has immune-mediated platelet destruction. PTP can be considered if platelet refractoriness continues despite the transfusion of HLA-matched platelets. IVIG appears to be an effective treatment, although plasma exchange, corticosteroids, and splenectomy may also be useful. Patients with acute bleeding and needing platelet support should receive platelets without the platelet-specific antigen, if possible. If random donor platelets are given, patients can develop severe reactions, including allergic reactions. Recurrence of PTP is rare. The incidence of PTP has greatly declined in jurisdictions where universal leukodepletion is performed.

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

Transfusion-associated graft-versus-host disease (T-GVHD) occurs when immunologically competent lymphocytes are introduced into a host who cannot destroy the donor lymphocytes. The immunocompetent donor lymphocytes engraft, host HLA antigen is presented to donor lymphocytes, and the activated lymphocytes attack host tissues. T-GVHD occurs after transfusion of nonirradiated cellular blood components, either in immune-compromised patients or when the blood donor and recipient share HLA antigens. T-GVHD has a much higher fatality rate than HSCT-related GVHD because the donor lymphocytes produce recipient bone marrow aplasia in addition to typical liver, gut, and skin manifestations of acute GVHD. In GVHD after bone marrow transplantation, the bone marrow is of donor origin, and bone marrow aplasia does not occur.

T-GVHD is fatal in more than 90% of cases, primarily because of aplasia of the recipient's bone marrow. It often occurs 8 to 10 days after transfusion with marked pancytopenia, as well as gut, skin, and liver GVHD. The signs and symptoms include nausea, vomiting, anorexia, fever, diarrhea, liver dysfunction, and erythroderma. Patients often die of infection and hemorrhage within 3 to 4 weeks. There is no effective treatment, with the possible exception of bone marrow transplantation, if T-GVHD is recognized early and a suitable donor can be found in a short time.

Reports have shown that haploidentical directed donor units of blood may produce fatal T-GVHD even in immunocompetent recipients. The use of irradiated blood (2500 cGy) is thus recommended

RISK GROUPS FOR TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

- Congenital T-cell defects (known or suspected)
- Immunologic immaturity (fetus or premature infant)
- Intrauterine transfusion
- Hematopoietic stem cell transplant
- Fludarabine treatment
- Haplotype sharing between donor and recipient
- Transfusions from blood relatives
- Human leukocyte antigen-matched platelets
- Granulocyte transfusions

in clinical situations in which T-GVHD is considered possible, such as when patients receive directed blood transfusions from their relatives. Leukocyte-reduction filters should not be used as prophylaxis against GVHD because the number of leukocytes needed to produce the disease is not known. Case reports of fatal T-GVHD in patients who received leukoreduced, but not irradiated, blood have been published. GVHD continues to be a rare, but extremely serious, complication of blood transfusion. From 2009 to 2013, two fatalities from T-GVHD were reported to the FDA. There is no clear evidence that prophylactic irradiation is indicated for patients with human immunodeficiency virus infection (see box on Risk Groups for Transfusion-Associated Graft-Versus-Host Disease). Of note, irradiation of RBCs causes membrane damage, permitting slow leakage of potassium and hemoglobin extracellularly. Nevertheless, rather than track which patients need irradiated blood, many centers provide universal irradiation of RBC components without adverse sequelae.

IRON OVERLOAD—HEMOSIDEROSIS

Transfusion-associated hemosiderosis is defined as a blood ferritin level of greater than 1000 mcg/L, with or without organ dysfunction, in the setting of repeated RBC transfusions. Iron loading from RBC transfusion is categorized by the ISBT as a transfusion reaction and is a common adverse consequence of chronic RBC transfusion. Further discussion of iron metabolism can be found in Chapter 36.

One milliliter of RBCs at a hematocrit of a typical RBC unit contains approximately 0.75 mg of iron. A unit of blood with 300 mL of RBCs thus contains approximately 225 mg of iron, and 4 units of blood contain ~1 g of iron, roughly the amount stored in the bone marrow. Men and nonmenstruating women lose only approximately 1 mg of iron each day. Continued use of transfusion therapy can thus result in the accumulation of excessive tissue stores of iron in individuals with hemolytic anemia, such as those with thalassemia or sickle cell disease (see Chapters 41, and Chapters 42 and 43, respectively), or ineffective hematopoiesis as in myelodysplastic syndromes (Chapter 61), in which iron is not lost from the body but is recycled. Over long periods, the iron that is stored in parenchymal cells results in oxidative injury and organ failure, particularly in the heart, liver, and endocrine organs. Iron chelation therapy is now widely used to mitigate positive iron balance. The availability of oral iron chelators such as deferasirox and deferiprone provides expanded access to iron chelation therapy.

HEMOVIGILANCE

Hemovigilance is defined by the International Haemovigilance Network as "A set of surveillance procedures covering the whole transfusion chain (from the collection of blood and its components to the follow-up of recipients), intended to collect and assess information on unexpected or undesirable effects resulting from the therapeutic use of labile blood products, and to prevent their occurrence or recurrence." Since the mid-1990s, in response to the "contaminated blood" scandals, many countries in the world have established national hemovigilance programs to which hospitals and blood establishments report untoward reactions and occurrences associated with blood transfusion and in some cases also plasma-derived products. Well-known examples are the professionally based SHOT (Serious Hazards of Transfusion, UK) and TRIP (Transfusion and Transplantation Related Incidents in Patients, The Netherlands), while Canada's Transfusion Transmitted Injuries Surveillance System, TTISS, is run by the public health agency and the French hemovigilance system by the regulator, the ANSM (Agence Nationale de Sécurité du Médicament et des Produits de Santé). In the United States, the National Healthcare Safety Network (NHSN) Hemovigilance Module was developed through a public-private partnership between the Centers for Disease Control and Prevention (CDC) and subject-matter experts convened by AABB (formerly the American Association of Blood Banks).

Importantly, these systems have legal safeguards to ensure that adverse reactions and events can be reported to them safely without risk of the institution or individual professionals being publicly identified or shamed. The collected data are reported publicly, provide transparency about the risks of transfusion, highlight risks, and make recommendations for improving safety.

Providing professionals in the health care facilities and blood establishments with standardized definitions and clear reporting instructions has been key in collecting data with the greatest possible potential for trend analysis, comparisons, and benchmarking. International definitions have been published by the International Society for Blood Transfusion in collaboration with the International Haemovigilance Network. The NHSN Hemovigilance Module provides standard criteria and definitions to participating facilities (http://www.cdc.gov/nhsn/PDFs/Biovigilance/BV-HV-protocol-current.pdf). Transfusion reactions are further classified by their severity and imputability—that is, the likelihood that the reaction is attributable to infusion of the blood product.

Healthcare facilities and blood establishments need to have protocols and provide training for staff in all relevant roles on how to handle blood products, correctly identify patients, recognize and respond to adverse reactions, and know what to report and how/to whom. Some establishments specifically qualify and revalidate nursing staff for performing blood transfusions. At best, a hemovigilance worker, also known as a transfusion practitioner, will be in post to support or run these activities (depending on institution size and local arrangements). Additional tasks are the development and overseeing of patient blood management activities and conducting audits of blood use.

Hemovigilance depends on clinicians and nursing staff considering the possibility of a transfusion reaction and reporting the signs and symptoms to the blood transfusion laboratory. The rate of such so-called spontaneous reports will generally be much lower than findings in clinical studies where active surveillance is in place, that is, where the outcome and associated symptoms are reported for every unit. When examining rates of reported transfusion reactions, it is essential to be aware of the method of data collection.

Traceability of a unit from donor to patient is essential, that is, ensuring that the blood establishment retains the record of donor identity for each unit and that transfusion facilities record (confirmed) transfusion of a unit to the patient or if a unit was not transfused, its final disposal. This allows for investigations in the (uncommon) event of a subsequent, potentially TTI in a donor or patient.

An early lesson from hemovigilance reporting was the data emerging from the SHOT scheme that showed that errors and notably "wrong blood" events (incorrect blood component transfused [IBCT]) more often caused more serious harm to patients than TTIs. Hemovigilance systems have also contributed to establishing the efficacy of safety interventions, for example, reduction in TRALI using plasma exclusively from male donors. They have the potential to identify emerging threats to transfusion safety, especially where events are uncommon, and are detectable only when large numbers of outcomes are evaluated in aggregate.

Although the earliest focus of hemovigilance was to monitor and improve the safety of clinical transfusion, this was followed by what has been called donor hemovigilance, “the systematic monitoring of adverse reactions and incidents in the whole chain of blood donor care, with a view to improving quality and safety for blood donors.” Alongside the centralizing and reporting of data on complications of blood donation, increasing research activity has demonstrated risk factors and shown the effectiveness of measures to reduce the occurrence of complications. The most frequent complication is dizziness or fainting (vasovagal reaction) during and following the donation of whole blood or blood components. By implementing best practices (e.g., an extra water drink shortly before donation, extra salt, social distraction), blood establishments can improve donors’ experience, which in turn increases the likelihood of future donations.

Both iron overload in chronically transfused patients and iron depletion blood donors, important longer-term complications of repeated transfusions and donations, remain challenging to capture and monitor in a meaningful way at the aggregate level. Chapter 37 discusses the management of iron overload of individual transfusion-dependent patients.

COMPLICATIONS ASSOCIATED WITH HEMATOPOIETIC STEM CELL INFUSION

Hematopoietic stem cells (HSCs), the most widely used cell therapy products, may be derived from bone marrow, peripheral blood, and umbilical cord blood. The infusion of HSCs carries the risk of the same types of transfusion reactions as with blood transfusions. However, additional risks are associated with HSC infusion, such as those related to cryopreservatives. In general, infusions of cryopreserved cells are more likely to cause reactions, as they contain higher concentrations of lysed RBCs and granulocytes than other blood products. For most reactions, it is difficult to identify the causative agent. Moreover, because of the irreplaceable nature of HSC products, higher risks may be tolerated. Only those reactions that are unique or more problematic for HSC infusions are discussed in this section. A summary of the reactions is given in Table 117.4.

Dimethyl Sulfoxide Toxicity

The most common reactions to HSC have been attributed to dimethyl sulfoxide (DMSO), the most widely used cryopreservative. A variety of symptoms are associated with DMSO infusion and are generally dose-dependent. A garlic odor commonly accompanies DMSO infusion, and nausea and vomiting are often reported. Additional DMSO-related symptoms include flushing, coughing, chest tightness, dyspnea, abdominal pain, hypotension, hypertension, cardiac toxicity (such as bradycardia and other arrhythmias), and rarely, neurologic toxicity (such as syncope and transient encephalopathy). Some cases of DMSO toxicity are thought to arise from the release of histamine. Most clinical services have protocols in place to limit the volume of DMSO that can be infused, such as setting an upper infusion limit of 1 g/kg/day, dividing HSC infusion doses, or washing HSC products to remove DMSO (this, however, may result in cellular loss).

Red Blood Cell Hemolysis

Although mismatched ABO and non-ABO blood groups do not prevent successful HSCT, these antigens (and their corresponding antibodies) can create problems during the transplant period. When considering incompatibilities within the ABO system, three scenarios are possible: (1) antibodies present in the recipient interact with incompatible cells present in the graft (major incompatibility), (2) antibodies present in the plasma portion of the graft mediate hemolysis of recipient RBCs (minor incompatibility), or (3) antibodies present in both the recipient and the donor interact with incompatible RBCs (bidirectional, or two-way, incompatibility). It has been shown that both major and bidirectional ABO incompatibility can delay stem cell engraftment. In such cases, anti-A and/or B antibodies suppress RBC precursors expressing these antigens, leading to reticulocytopenia and prolonged anemia. In the most severe form of this process, HSC recipients can develop pure RBC aplasia, a condition wherein bone marrow shows a virtual absence of immature erythroid elements more than 3 months posttransplantation. In cases of either delayed engraftment or pure RBC aplasia, patients are dependent on RBC transfusions for prolonged periods of time.

Another risk factor associated with HSC infusion is the possibility of RBC hemolysis. Both ABO and non-ABO antibodies are capable of mediating RBC lysis. In such conditions, preformed antibodies in either the recipient or HSC plasma can cause accelerated clearance of incompatible RBCs by either intra- or extravascular mechanisms. Presentation of hemolytic transfusion reactions immediately after HSC infusion is no different from that of typical transfusion reactions. Policies and protocols should be in place to prevent postinfusion HSC-related hemolysis—for example, plasma depletion of HSC products (in cases of minor mismatch and bidirectional ABO incompatibility), limiting the infusion of incompatible RBCs (in cases of major mismatch and bidirectional ABO), hydration of patients, and prospective monitoring for hemolysis. The reader is also referred to the chapters on stem cell graft harvesting and processing (Chapters 102 and 103).

TABLE 117.4 **Common Hematopoietic Stem Cell Infusion Reactions**

Types	Presentations	Treatment and Prevention
DMSO toxicity	Halitosis, nausea, vomiting, flushing, coughing, chest tightness, dyspnea, abdominal pain, hypotension, hypertension, cardiac toxicity (such as bradycardia and other arrhythmias), and rarely neurologic toxicity, such as syncope and transient encephalopathy	Antihistamine Antiemetics Limiting DMSO infusion volume
Minor ABO mismatch	Delayed hemolysis (1–2 weeks post HSC infusion)	Plasma depletion of HSC product RBC transfusion support compatible with donor and recipient Monitor for hemolysis RBC exchange with donor- and recipient-compatible blood if massive hemolysis
Major ABO mismatch	Hemolysis at the time of infusion Delayed RBC engraftment	Limiting the infusion of incompatible RBC Hydration Monitor for RBC engraftment Modify immunosuppression Plasmapheresis to remove isohemagglutinins if significant RBC engraftment delay

DMSO, Dimethyl sulfoxide; *HSC*, hematopoietic stem cell; *RBC* , red blood cell

CHAPTER 118

TRANSFUSION-TRANSMITTED DISEASES

Lauren A. Crowder and Susan L. Stramer

Adverse reactions following blood transfusion reflect immunologic, pathophysiologic, and microbiologic events. This chapter presents information about transfusion-associated viral, bacterial, parasitic, and prion infections and discusses a number of emerging agents including severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Transfusion-transmitted infection risk mitigation through blood donor screening and blood testing strategies are presented.[1] The boxed discussions provide insights into interventions aimed at reducing risk from known and emerging threats and new technologies for reducing or eliminating microbial contamination. Red cell, platelet, and plasma transfusions represent important therapeutic modalities for appropriately selected patients. Awareness of the hazards of transfusion and the rate at which these events occur should enable physicians to better determine the benefit/risk ratios when prescribing transfusions.

HEPATITIS VIRUSES

The hepatitis viruses can be classified according to their predominant modes of transmission, parenteral and enteric, with the parenterally transmitted agents, hepatitis B virus (HBV) and hepatitis C virus (HCV) dominating concerns about transfusion transmission because many individuals unknowingly infected with these agents become asymptomatic chronic carriers and may make blood donations.

Parenterally-Transmitted Hepatitides

Hepatitis B

HBV is a deoxyribonucleic acid (DNA) virus in the family *Hepadnaviridae*. The infectious virion is occasionally referred to as the Dane particle and has surface and core components, surface antigen (HBsAg) and core antigen (HBcAg), respectively. Epitopes on the viral surface provide a basis for epidemiologic studies and consist of the HBsAg "a," d/y, and w/r determinants. However, this approach is being replaced by genotyping and DNA sequencing methods. Recombinant vaccines containing the "a" determinant confer protective immunity to a high proportion of vaccinees and are dramatically altering the incidence and prevalence of HBV infection in the general population where they are in wide use and consequently also impact the frequency of HBV infection in the donor population.

The average incubation period (the time from infection to liver enzyme elevation and symptomatic hepatitis) is 59 days (range, 5 to 12 weeks) but may be as long as 6 months. Symptoms, which occur in 30% to 50% of infected persons aged 5 years and older, include fatigue, anorexia, nausea, vomiting, jaundice, dark urine, light stools, arthralgias, rashes, vasculitis, and glomerulonephritis. The risk for progression to chronic infection is inversely related to age at infection. HBV infection becomes chronic in more than 90% of infants, 25% to 50% of children 1 to 5 years of age, and fewer than 5% of older children and adults. Approximately 5% of the US population has serologic evidence of prior HBV infection (antibodies against HBcAg [anti-HBc] reactive). From the mid-1980s with increasing immunization in early childhood, the incidence of acute HBV infection has decreased. In 2017, 46 states reported over 3400 cases of acute HBV to the US Centers for Disease Control and Prevention (CDC), or 1.1 case per 100,000 population. Due to underreporting and asymptomatic cases that are not diagnosed and reported, estimates of the actual number of acute cases in 2017 is over 22,000. An additional 13,300 cases of chronic HBV cases were reported and approximately 862,000 people are estimated to be living with chronic HBV infection.[2] Approximately 1700 deaths occurred in 2017 resulting from hepatitis B and its complications.

Based largely on data from parenteral exposures of health care workers, HBV is 100 times more infectious than human immunodeficiency virus (HIV) and 10 times more infectious than HCV. The predominant mode of transmission to adults and adolescents is through sexual contact. Forty percent have infected partners, 15% are males having sex with other males, injecting drug users account for 14% of cases, and one-third have no identifiable risk. A recent study of risk factors in blood donors found to be infected with HBV found that of 292 infected donors surveyed, the characteristics most frequently associated with infection were living abroad or having immigrated to the United States (51% vs. controls at 6%), a family member infected with hepatitis (15% vs. 2%), having been in a jail or detention for 3 nights or more (19% vs. 5%), and having taken illegal drugs (20% vs. 12%).[3]

HBsAg is detectable in blood approximately 4 weeks (30 to 60 days) after infection. Subsequently, immunoglobulin M (IgM) anti-HBc antibodies appear coincident with symptom onset. High viral titers present at that time decline subsequently. HBsAg persists transiently in acute infections for up to 4 months (average 63 days). More recent data using extremely sensitive HBsAg assays for blood donation screening show the mean period of HBsAg duration to be 43 days.[4] Antibodies against HBsAg (anti-HBs) develop subsequently and are generally thought to protect against reinfection although recent studies on blood donors have identified a few breakthrough cases of infection. These cases were mainly caused by HBV genotypes differing from that of the vaccine strain and were mild and self-limited.[5] Such donations were not detected by HBsAg blood donation screening but required more sensitive HBV DNA screening.

Some anti-HBc–positive and HBsAg-negative individuals have circulating HBV DNA, and this pattern defines so-called occult HBV infection (OBI). In rare cases, OBI may be accompanied by anti-HBs, usually at levels below 200 mIU per mL. Donors with OBI may transmit HBV via blood transfusion, but the frequency of such infection is low, and seems to be absent if anti-HBs are present.[6] Although anti-HBs usually confers immunity to reinfection, sufficient virus remains in the liver to transmit HBV following liver transplant from anti-HBs–positive donors through reactivation under intense immunosuppression.

It should be noted that the FDA has eliminated the requirement to ask blood donors about a history of viral hepatitis, effective May 2016.[7] The detection of HBV DNA is performed by nucleic acid testing (NAT) in minipools of 6 to 16 donations each as now required per Food and Drug Administration (FDA) Guidance, Use of Nucleic Acid Tests on Pooled and Individual Samples from Donors of Whole Blood and Blood Components, including Source Plasma, to Reduce the Risk of Transmission of Hepatitis B Virus (www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/Guidances/default.htm, October 2013) and made final in updates to the Code of Federal Regulations.[7] The risk for HBV transmission per unit in the United States has recently decreased substantially as a result of very sensitive HBsAg testing, the implementation of NAT, and a recent

TABLE 118.1 **Risk for Transfusion-Transmitted Diseases in the United States**

Pathogenic Agent or Disease	Average Estimated Risk Per Unit
Hepatitis A	Rare
Hepatitis B	1 per million
Hepatitis C	1 per 2 million
Human immunodeficiency virus	1 per 1.6 million
Human T-lymphotropic viruses 1, 2	1 per 3.3 million
Cytomegalovirus	Infrequent in screened products; 1% in unscreened products
Parvovirus B19	Rare
West Nile virus	Rare
Malaria	0–3 cases per year
Babesiosis	1 per 18,000 in highly endemic regions; 1 per 100,000 endemic regions overall
Chagas disease	20 transfusion-associated cases reported
Creutzfeldt-Jakob disease	4 vCJD transfusion-associated cases reported Transfusion transmission of non-variant CJD has not been shown
Bacterial Contamination:	
Red cells	1 per 30,000
Septic reactions	1 per 500,000–1 per 10 million
Platelets	1 per 3000–1 per 8000
Septic reaction	1 per 107,000
Emerging Infections:	Risk unknown
Arboviruses including dengue viruses, chikungunya and Zika viruses	
Pandemic influenza viruses (H5N1, H1N1)	

vCJD, Variant Creutzfeldt-Jakob disease.

decline in the incidence of HBV infections among donors undoubtedly because of universal vaccination (Table 118.1).[4,5,8,9] Before NAT implementation, most contemporary HBV transfusion-transmitted infections were attributable to blood donations from asymptomatic donors during acute infection preceding the development of detectable HBsAg. Early in infection, HBV replicates relatively slowly with a doubling time of approximately 2.6 days. The current window period between infection and the detection of HBV DNA by NAT ranges from 30 to 38 days depending on the infectious dose, which, early in infection, is estimated to be between 1 and 10 copies per mL.[10] Since the implementation of HBV NAT in the United States, there have been no documented cases of breakthrough HBV transfusion transmissions. The per unit residual risk for donations to the American Red Cross was estimated to be 1 per 843,000 to 1 per 1,208,000 in 2013 and 1 per 1,529,000 in 2015 to 2016 using an 18.5 day window period and weighted for all donors (first-time and repeat).[11] Residual risks of 1 per million using the same methods are documented from large multicenter national studies for 2018 to 2019.[12,13]

There is evidence that some HBsAg assays will not detect all HBsAg and HBc genetic variants of HBV. Because all blood donations are screened by HBV NAT, HBsAg, and anti-HBc, it is unlikely that any mutant strain of HBV would go undetected in the United States. Among 12.8 million blood donors to the American Red Cross during 2009 to 2011, 1 per 9337 were infected with HBV. Of these, 1090 were positive for HBsAg, with or without HBV DNA (1 per 11,736), and only 5 were identified solely by NAT in minipools (1 per 2.55 million).[8] However, more recent data, also from the American Red Cross, demonstrate the HBV DNA detection rate of seronegative donations by NAT to be 1 per 770,000 donations.[11] NAT on individual donation aliquots has the potential to reduce the risk for transfusion-transmitted HBV further by detecting newly infected donors slightly earlier than either minipool-NAT or HBsAg tests licensed for blood donor screening, but the additional cost of individual donation-NAT in the United States would be high with very little to no demonstrable clinical benefit.

Hepatitis D

Hepatitis D virus (HDV) was originally called the delta agent. It is a defective ribonucleic acid (RNA)–containing passenger virus that requires active synthesis of HBsAg to act as a "helper" for assembly of HDV virions. As many as 10% of HBV infections are accompanied by HDV worldwide. Its prevalence is very low in the United States but higher in intravenous drug users. HDV superinfection of chronic HBV carriers is associated with worsened chronic sequelae and with fulminant hepatitis. Screening for HBV acts synergistically to prevent transfusion-associated HDV cases by identifying donors that are co-infected with HBV and HDV. There has never been an HBV-HDV–related transfusion transmission reported.

Hepatitis C

HCV is an RNA virus in the family *Flaviviridae*, genus *Hepacivirus*. There are six genotypes that share similar epidemiology, pathogenesis, and natural histories. In the United States, genotype 1 causes 75% of infections, genotypes 2 or 3 causing 15% to 20% of infections, and genotypes 4, 5, and 6 causing less than 5% of infections. Genotype 1 responds relatively poorly to traditional treatment regimens using pegylated interferon combined with oral doses of ribavirin compared with genotypes 2 and 3; the overall cure rate for all genotypes using this regimen was no better than 40% to 50%. HCV protease inhibitors (direct acting antivirals) are materially improving these rates. Two oral regimens of Harvoni and Viekira Pak are now the standard of care in the United States, and result in a sustained virologic response of greater than 90% (https://www.cdc.gov/hepatitis/statistics/2017surveillance/index.htm#hepatitisB, Viral Hepatitis–2017 Surveillance).

HCV is distinguished by a low rate of recognized acute infection and by a high rate of chronic infection, with substantial morbidity and mortality over long periods of observation as a result. The CDC estimates that there were 2.4 million people living with chronic HCV infections in 2017.

The most common source of HCV acquisition is intravenous drug use. The prevalence of HCV in US adults (20 to 59 years old) with any history of illegal intravenous drug use is greater than 45%. Other risks include blood transfusion before donor serologic screening began in 1990, exposure in health care settings, including through dialysis, among infants born to HCV-infected mothers, and tattoos in unregulated settings. In a large series, 15% to 30% of patients report no risk factors. Vertical transmission occurs in 3% to 7% of infants of mothers with active infections. In contrast to HBV, sexual transmission is an inefficient route of infection and much less often reported but was found to be the most likely mode of transmission of HCV among HIV-infected men who have sex with men (MSM) in New York City. In 2012 the CDC recommended that individuals born during 1945 to 1965 have one-time HCV screening since among all persons living with HCV infection, about 75% were born during this time. Such individuals have a 3% prevalence, which is five times higher than the prevalence seen in adults born in other years. Among blood donors, 0.03% have confirmed-positive HCV test results. There have been studies on risk factors among HCV-infected blood donors, and despite policies requiring deferral of injection drug users, such use is the most common risk factor.[3,14] Of 316 blood donors followed who were HCV-confirmed positive, risks identified via a retrospective questionnaire revealed risks versus control donors of illegal drug use (37% vs. <1% for controls), followed by jail or detention (57% vs. 5%), history of a blood transfusion before screening (18% vs. 7%), and living in a household with someone having hepatitis (15% vs. 2%).

At most 20% to 30% of newly infected persons develop recognizable symptoms during acute HCV infection. Some 20% of infected individuals clear their infection over a relatively short initial period, remaining antibody-positive but RNA-negative. Chronic infection develops in 75% to 85% of persons infected after 45 years of age and in 50% to 60% of those infected as children or young adults. Chronic HCV infection progresses to cirrhosis in 15% to 30% over 30 years of observation. Hepatocellular carcinoma occurs in 1% to 4% per year in those with cirrhosis. HCV is among the most prevalent causes of chronic hepatitis, cirrhosis, and primary liver cancer in the developed world and is the most common indication for liver transplantation in the United States, resulting in around 2400 procedures annually.

A single positive anti-HCV result cannot distinguish between acute and chronic HCV infection or between current or cleared infection. In 2012 laboratory criteria for the confirmation of anti-HCV reactivity were modified to add one specific assay including RNA detection, using a supplemental anti-HCV assay (as available) or a single value above a specific threshold on the screening test.[15] The risk for posttransfusion HCV infection declined progressively with the introduction of surrogate markers for non-A, non-B hepatitis in the 1980s (alanine aminotransferase [ALT] and anti-HBc) and of serologic testing for HCV antibodies in May 1990, followed sequentially by improved serologic testing and NAT. The seronegative-window period for the first-generation HCV antibody test extended to 6 months from infection but was reduced to 82 and 70 days with second- and third-generation assays, respectively. NAT further reduced the window period to approximately 7 days. The risk per unit declined from an estimated 1 per 276,000 units to 1 per 2,600,000 units from 2007 to 2016 and in 2018 to 2019 in larger multicenter national studies to 1 per 2 million weighted for all donations from both first-time and repeat donors.[11,12]

Like HBV, in the United States, testing for HCV RNA has used NAT in small minipools combining aliquots from 16 to 24 donations (currently 6 to 16). Loss of test sensitivity because of sample pooling was tolerable given the rapid increase or burst of HCV viremia before antibody seroconversion (estimated doubling time of 10.8 hours in that period during the 40- to 50-day window period) and the high titer of viremia that remains preceding antibody seroconversion. However, the rest of the world (except the United States, Canada, the United Kingdom, and most of Germany) has implemented NAT for screening individual donation samples intended for transfusion. The HCV RNA yield by NAT in seronegative donations using data from the American Red Cross is 1 per 270,000 donations.[11]

As an alternative to NAT assays, enzyme immunoassays (EIAs) have been developed that detect HCV HBcAg in serum or plasma, either as an individual analyte in parallel with antibody assays or as HCV antigen-antibody combination assays. These tests reduce the pre-seroconversion window period and were adopted in some developing countries. They are less sensitive than HCV NAT, are not approved for blood donor screening in the United States, and use has decreased significantly.[16] Since the implementation of NAT, reports of transfusion-transmitted HCV are very infrequent.

The high seroprevalence of HCV at the onset of serology screening in the early 1990s, the prolonged interval between infection and clinical manifestations, and the relatively high rate of HCV clinical sequelae prompted blood collection facilities and hospitals to conduct "look-back" notification of previous recipients of blood given by donors found on subsequent donations to be HCV infected. Look-back was subsequently made mandatory in companion rules from FDA and the Centers for Medicare and Medicaid Services. In general, HCV look-back programs found half or fewer of targeted transfused individuals alive but were able to find both seropositive and RNA-positive recipients who were unaware of their status. This population has benefited significantly from identification and subsequent treatment with the advent of curative direct-acting antivirals.

Enterically Transmitted Hepatitides

Hepatitis A

The hepatitis A virus (HAV), a nonenveloped picornavirus, genus *Hepatovirus*, is transmitted predominantly by the fecal-oral route, with an average incubation period of 28 days (range, 15 to 50 days) with signs or symptoms persisting for less than 2 months. The incidence of HAV infection in the United States fell by 76% between 1997 and 2003 after the recommendation for targeted immunization of members in high-risk communities. Populations at risk include those in areas where extended community outbreaks occur and children living in states that have high and intermediate rates of disease, staff and residents of closed communities, close personal contacts of cases, the staff and parents of children in daycare centers, and those with common-source exposure to infected food or water. For many sporadic cases there is no recognized source. HAV is self-limited with no chronic carrier state, but approximately 10% to 15% of infected individuals develop a more prolonged or relapsing illness. It is the most frequent cause of hepatitis among children under 11 years of age.

Transfusion-related transmission, although rare, is caused by a blood donation from a recently infected, asymptomatic, viremic individual. The peak viremia occurs 2 weeks before onset of jaundice or elevation of hepatocellular enzymes and persists for a median period of 42 days (range, up to 59 days). The virus is quite resistant to many inactivation procedures, including the pathogen-reduction procedures being developed for cellular blood components (e.g., licensed psoralens or investigational riboflavin, both with ultraviolet [UV] irradiation) and fresh-frozen plasma (solvent/detergent and methylene blue). Transmission by clotting-factor concentrates treated with the solvent/detergent pathogen-reduction process occurred in the 1990s, but not thereafter. Plasma for further manufacture is routinely screened for HAV RNA by pooled NAT.

A 120-day deferral is recommended after exposure to HAV during community outbreaks to prevent transfusion transmission. Screening for HAV is not done for donations of blood for transfusion.

While the average number of annual HAV infections reported to CDC in recent years has declined substantially compared to 2000, fluctuations have occurred in the last 20 years due to large outbreaks. After a long downward trend, the first increase between 2012 and 2013 (1562 and 1781 reported cases, respectively) was due to a large multi-state outbreak associated with pomegranate arils imported from Turkey.[17] Between 2015 and 2016, the reported cases again increased by 44.4% from 1390 in 2015 to 2007 cases in 2016. The 2016 increase was due to two hepatitis A outbreaks, each of which was linked to imported foods. Substantial increases in incident cases of hepatitis A occurred in 2017 and 2018 (3366 and 12,474 reported cases, respectively) due to ongoing outbreaks reported to CDC among people who use drugs and people experiencing homelessness as well as outbreaks among MSM.[18,19]

Hepatitis E

The hepatitis E virus (HEV) is a small, nonenveloped single-stranded RNA virus in the *Hepeviridae* family. HEV was first recognized in the 1980s in Afghanistan among soldiers with unexplained hepatitis. There is a single serotype but at least four genotypes with differing geographic distributions and epidemiologic patterns. Genotypes 1 and 2 are generally associated with large, water-borne (fecal-orally transmitted) outbreaks in less developed tropical countries. Illness is usually self-limited but can be lethal in pregnant women, their fetuses, and patients with chronic liver disease. Genotypes 3 and 4 appear to be animal viruses that result in zoonotic infection of humans, most often through consumption of inadequately cooked pork products. Genotype 3 seems to be widely distributed and is present in developed countries, whereas genotype 4 seems to be more common in certain Asian countries. Transfusion-related transmission, mostly of serotype 3, has been well-documented in Japan, France, England, the Netherlands, and Spain.[20]

Recent studies suggest a wide range of seroprevalence rates, but some of the variability may be attributable to the differences in performance characteristics of the tests used and some to dietary habits. Most studies indicate a cohort effect, with prevalence rates increasing with age. Transfusion infectivity is logically associated with the presence of detectable viral RNA in the plasma and the frequency of this finding varies between 1 in 1000 to 1 in 10,000 donations.

In a large study in England,[21] 225,000 donations were tested and 79, or 1 in 2848, were found to be positive when tested for HEV RNA. For 43 of these, recipient tracing was possible and 18 (42%) showed evidence of transfusion-transmitted infection. A North American study screened 101,489 donations from Canada and the United States for HEV RNA and reported 14 positive donors, or 1 in 7300, all with low viral loads (ranging from 20 to 3080 copies/mL) consistent with a prior US study finding 7.7% of donors anti-HEV positive but only two of approximately 19,000 that were RNA positive.[22,23] Although the Canadian prevalence was fourfold higher than in the United States, quantitative and risk-based analysis found testing to not be cost effective. A current broader concern is the finding that highly immunosuppressed patients (such as solid-organ transplant recipients) do develop chronic HEV infections with long-term clinical sequelae, although these have not been specifically linked to infection via transfusion. While testing is standard in some European countries and Japan, where incidence rates are higher and transfusion transmissions well documented, in the United States and Canada routine testing is currently not recommended due to the absence of recognized transfusion transmission.

Non–A-E Hepatitis

Cases of posttransfusion hepatitis only rarely if ever occur but there remains speculation that undiscovered hepatitis agents exist. A small but consistent percentage of community-acquired hepatitis cases test negative for known hepatitis viruses, some cirrhosis is classified as "cryptogenic," an etiologic agent for hepatitis-associated aplastic anemia (Chapter 31) eludes description, and the cause of some cases of acute liver failure remains elusive. Several candidate agents have been proposed as non–A-E hepatitis viruses. None of these agents have been shown to be pathogenic and are instead likely commensal and nonpathogenic.

GBV-C (initially called hepatitis G virus) is a flavivirus with no confirmed disease association that is transmitted parenterally, including frequently by transfusion. Of interest, GBV-C infection may delay progression of disease in those co-infected with HIV, which has led to studies of the interactions between these viruses.[24]

From 1% to 4% of US blood donors are viremic compared with 15% to 20% of intravenous drug users who have detectable GBV-C RNA. Infection occurs frequently among those infected with HCV and HIV. More people have antibodies against the E2 envelope protein, in the absence of RNA, suggesting viral clearance. GBV-C has not been shown to cause liver disease or other morbidities, and hence there is no consideration of donor screening at this time. GBV-C is now referred to as a human pegivirus. A second human pegivirus has recently been described associated with HCV likely as a result of an acute parenteral co-infection event, but again, has not been associated with hepatitis or any pathology. This virus was identified by next generation sequencing.[25] Likely other such commensal agents will continue to be identified by the use of sophisticated molecular techniques (Chapter 3).

The torque teno virus (TTV) complex is a genetically diverse group of nonenveloped DNA viruses in the family *Circoviridae*, which was discovered in 1997. They cause viremia, and they are transmitted by transfusion, but they cause no recognized liver disease or other clinical illness.

SEN virus (SENV), another member of the *Circoviridae*, was described using degenerate polymerase chain reaction (PCR) primers while working with TTV. After an initial report associating SENV variants in two patients with transfusion-associated non–A-E hepatitis, subsequent epidemiologic studies have failed to link SENV with clinical hepatitis.

RETROVIRAL INFECTIONS

Human Immunodeficiency Virus

The HIVs type 1 and type 2 (HIV-1 and HIV-2) are retroviruses of the family *Retroviridae*, genus *Lentivirus*, and the etiologic agents of the acquired immunodeficiency syndrome (AIDS). They are enveloped viruses with two linear, positive-sense RNA molecules, 9.2 kb in length. The predominant transmission mechanisms are sexual, perinatal, and parenteral. An acute retroviral syndrome may be seen around 21 days after infection, although this period may range from 5 to 70 days and may involve fever, lymphadenopathy, and rash. If untreated, the incubation period for full-blown AIDS is measured in years. Molecular characterization divides HIV-1 into three groups: group M (main), group O (outliers), and group N (non-M/O). Group M subtype B infections predominate in the United States; only 3% of HIV-positive blood donors have non-B strains. Very rare group O infections have been detected in the United States among patients who were born, lived, or had sexual contact in endemic regions of West and Central Africa. HIV-2 infected persons in the United States are rare (less than 1% of HIV cases diagnosed annually) and have, for the most part, been infected after heterosexual transmission in West African emigrants or residents. HIV-2 disease requires a longer time to evolve and is less severe than that from HIV-1 There have been five confirmed cases of HIV-2 infection among blood donors in the United States.

In 2016 CDC estimated that a total of 1.1 million people in the United States 13 years or older were living with HIV infection, approximately 1 per 300 Americans, with 14% of those unaware of their infection. Of the approximately 38,000 new diagnoses in 2018, the highest number of new infections occurred in those 25 to 29 years old (20%), in predominately African Americans (40%). MSM continue to bear the greatest burden of HIV infection among all racial and ethnic groups. Although MSM represent 6% of the US population, in 2018 MSM accounted for nearly 82% of all new HIV infections in males and over 65% of all new HIV infections. Antiretroviral therapy for HIV treatment has improved dramatically since the advent of combination therapy in 1996, even against multidrug resistant viruses. HIV-associated morbidity and mortality have significantly been reduced so that HIV treatment has converted HIV infection to a chronic, versus a fatal, disease.

Antibody testing of blood donors detects both HIV-1 and its variants and HIV-2.[26] Antibody testing for HIV-1 began in 1985, with the addition of HIV-2 in 1992 (although HIV-1 tests before that time detected most HIV-2 infections arising from over 60% sequence homology between the two viruses) and for HIV-1 group O in 2006.

Both serologic testing and NAT are performed on every blood donation. First-generation antibody tests had a window period (time between infection and detection) of 45 days on average but has decreased significantly as tests became more sensitive leading to less than a 20-day window period. HIV-1 NAT, implemented in 1999 (initially in duplex tests with HCV performed in pools of 6 to 16 donations), detects RNA at a minimum concentration of approximately 5 copies per milliliter (50% lower limit of detection) leaving about a 9-day window period of risk in which an infected donor could donate and not be detected by any test in current use. Rare genetic variants of HIV may escape NAT detection when nucleotide sequence changes affect NAT primer or probe binding sites, but the vast majority of these infections will be detected serologically. Further, tests are now designed to detect two or more separate sequences representing different viral regions. Currently, the frequency of confirmed-positive test results for antibodies to HIV is 1.65 per 100,000 donations (1:61,000). Almost all of these are also RNA-positive as the finding of an infected donor with low-level RNA levels is very rare (on the order of 2%). One donation per 2.1 million is confirmed positive for RNA in the absence of antibody (NAT yield).[11]

To eliminate donations in the window period between exposure and test positivity, each blood donor is asked at each donation about exposure risks using questions developed in the early to mid-1980s, subsequent to the first reports of AIDS in hemophiliacs and transfusion recipients. These initial interventions targeted blood donations from homosexually active men and intravenous drug users, substantially reducing the transmission risk between 1983 and 1985. Five clusters of transfusion transmissions have been documented subsequent to the introduction of NAT, three before 2002 and one in 2008.[10,27] It is of interest to note that in two cases, although the transfused plasma component transmitted HIV, the corresponding red cell component did not. Modeling suggests a residual risk for HIV transmission persists at approximately one transmission per 1.5 million donations, because NAT cannot detect HIV infection during the immunosilent 9-day eclipse phase between infection and test reactivity. Processing and quarantine procedural errors do not now appear to be a risk for transmission of HIV via transfusion. Fourth-generation tests combine HIV-1/2 antibody and HIV antigen detection and detect almost 90% of infections detected by NAT. Their role is expanding worldwide even in countries that use HIV-1 NAT. In 2014 the CDC published revised guidelines for laboratory diagnosis of HIV infection (https://doi.org/10.15620/cdc.23447).[28]

Recent studies have shown that the predominant risk factors for HIV infection among 149 male infected blood donors surveyed retrospectively continues to be a history of MSM behavior (62% in cases vs. 2% in controls) or of a male having sex with an HIV-positive individual (26% in cases and none in controls). Of note, 50% of MSM activity occurred within the last 12 months. Although in the past, intravenous drug use was also a prominent risk factor, this has decreased in prominence (24% in cases vs. 5% in controls).[3]

In 2015, the Transfusion-Transmissible Infections Monitoring System (TTIMS) was established by the FDA, National Heart, Lung and Blood Institute (NHLBI), and the Office of the Assistant Secretary of Health (OASH) to establish a comprehensive monitoring program for transfusion-transmissible infections in the United States. Of primary focus for the first years of the program was the changing prevalence and incidence rates of HIV (as well as HCV and HBV) before and after MSM policy changes enacted by US blood centers following guidance changes by the FDA. Recent reports from the system show no marked changes in prevalence, incidence, residual risk, or recency of HIV infection during the 4 years surrounding policy changes, accounting for over 27.5 million donations from 9.4 million donors.[12,13,29–31] In April 2020, in response to the SARS-CoV-2 pandemic, the US FDA updated their 2015 guidance reducing the deferral period of MSM from 1 year since last MSM activity, as outlined in the 2015 guidance, to 3 months since last activity.[32] The TTIMS program will continue to monitor changes in screening and testing for TTIs following this policy change as well.

Current issues of concern related to HIV deferrals and testing include individuals on anti-retroviral therapy and those on post-exposure and pre-exposure prophylaxis. Initial reports show that individuals on ART or PrEP are part of the US donor population and that improved strategies need to be developed to encourage disclosure of these therapies and decrease test-seeking behaviors.[33]

Most consider the blood supply in the developed world to be at its highest historical safety level. This reflects incremental improvements in donor selection and history screening, blood testing, and process control that span four decades. For years, blood collection professionals and government regulators formulated blood safety policy decisions in an apparent aim to achieve a zero-risk blood supply. In part, this reflects the perceived delayed response of the transfusion medicine community in the early 1980s to the emergence of HIV in the blood supply and the recognition of the scope and severity of post-transfusion non-A, non-B hepatitis (subsequently hepatitis C [HCV]) following that. It reflects also the “dread fear” associated with transfusion-associated HIV. This reaction is seen when devastating, unpredictable, and stigmatizing events threaten potential victims who have little ability to escape the risk. This fear was validated by numerous transfusion-related HIV cases. It was amplified by widely publicized lawsuits, indictments, and criminal convictions of health ministers and policy makers in the 1980s and 1990s (*l’affaire du sang contaminé* in France addressing HIV and Canada’s Royal Commission of Inquiry on the Blood System into blood collection agencies’ response to non-A, non-B hepatitis risk) (Fig. 118.1). (See box on Blood Safety Decision Making.)

Human T-Lymphotropic Virus-1 and Virus-2

Human T-lymphotropic virus-1 (HTLV-1) and HTLV-2 are closely related delta retroviruses with 60% to 70% sequence homology and shared tropism for T-lymphocytes. In contrast to HIV, HTLV is rarely present in cell-free plasma and shows little active replication in infected humans. HTLV-1 is distributed worldwide, with endemic foci in southern Japan, the Caribbean, certain parts of South America, Africa, the Middle East, and Melanesia. HTLV-2 is endemic among Amerindians in both North and South America and African Pygmies. An epidemic of HTLV-2 infections has occurred over the past 40 to 50 years among intravenous drug users in the United States, Brazil, and Europe. Transmission of both HTLV-1 and HTLV-2 occurs by parenteral exposures, sexual contact, and by vertical transmission from mother to child during pregnancy and breastfeeding.

Diseases associated with HTLV-1 infection include adult T-cell leukemia/lymphoma (ATL), HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP), lymphocytic pneumonitis, uveitis, polymyositis, and arthritis. HTLV-2 does not appear to cause hematologic malignancies but has been associated with HAM/TSP and linked to a higher rate of common infections such as acute bronchitis, pneumonia, and urinary tract infections, suggesting a subtle immunomodulatory effect of the virus.[46]

ATL occurs in only 1% to 5% of infected persons following a latent period of decades. The illness is characterized by malignant lymphocytosis and leukemia, lymphadenopathy, hepatomegaly, abnormal liver function test results, splenomegaly, skin lesions, bone lesions, and hypercalcemia (Chapter 89). HAM/TSP occurs in approximately 2% of individuals infected with HTLV-1 and HTLV-2. Patients with transfusion-associated HAM/TSP develop neurologic symptoms rather more rapidly, at a median of 3.3 years after transfusion. This illness is characterized by slowly progressive chronic spastic paraparesis, lower limb weakness, urinary incontinence, impotence, sensory disturbances, low back pain, hyperreflexia, and impaired vibration sense.

Blood donor screening for HTLV-1 antibodies began in 1988, and more sensitive combination HTLV-1/2 assays that detect close to 100% of HTLV-2 infections were introduced in 1998. The prevalence of HTLV confirmed-positive donors decreased approximately 10-fold during the 1990s and continues to decrease to the current value of 0.002%. The rate is three-fold higher in female compared with male donors. Incident infections are rare in repeat donors, an observation that has led to one-time testing of donors in some European countries, but an incidence of 3 per million donor years of follow up is felt by some to be too high for adoption of this strategy in the United States. Cell-free components such as plasma and cryoprecipitate do not transmit HTLV, and less than 30% of infected cellular components transmit. The residual risk for transfusion-associated HTLV infection using contemporary serologic testing is approximately 1 per 3.3 million donations, but since the initiation of testing using these contemporary tests, there has not been a breakthrough HTLV infection by transfusion. The contribution of blood-donor serologic testing to this low residual risk is confounded by the effect of effective leukoreduction that reduces HTLV-1 copy numbers in red blood cell (RBC) concentrates by up to 6 logs, to below the infectious dose of 10^7 to 10^8 infected cells per unit (one of a number of arguments used in support of universal leukoreduction of blood components).

BLOOD SAFETY DECISION MAKING

Not surprisingly, from the 1980s until now, donor deferrals and blood-testing interventions have been rapidly, successively, and additively implemented for emerging and theoretical risks. Collection facilities introduced antibody testing to the HBcAg of HBV (anti-HBc) and ALT testing as surrogates for non-A, non-B hepatitis, HIV-1 p24 antigen testing, then NAT for hepatitis C and HIV and subsequently HBV, extensive deferrals for the risks attending transmissible spongiform encephalopathies (TSEs), NAT for West Nile virus (WNV), and antibody testing for *Trypanosoma cruzi*, among many others. The cost-benefit estimates for some of these interventions exceeded generally accepted thresholds by orders of magnitude, but this did not deter their adoption. In general, the implementation of these measures was undertaken in practice and in cost by the blood providers, but it is unlikely that this reactive approach can be sustained in the current health care–reform environment and in the face of declining funding for blood providers, at least in the United States.[34]

After HIV entered the blood supply, application of a stringent adaptation of the precautionary principle (originally promulgated for environmental protection, not transfusion safety) pushed decision making toward avoidance of all risks. The precautionary principle promotes implementation of measures to mitigate risk even if evidence of a risk is incomplete. It is supposed to be tempered by proportionality; that is, any measures adopted are to be proportional to the risk and with those used in similar circumstances, but some have argued that this has not been the case with blood safety measures, at least by the metric of cost-benefit. Nevertheless, although in potential conflict with evidence-based decision making, this approach resonated with policy advocates charged with transfusion safety. In contrast, when the risk for transfusion transmission of variant Creutzfeldt-Jakob (vCJD) disease (the human form of bovine spongiform encephalopathy, BSE) emerged as theoretical, modeling was used to balance the perceived risk against the impact of extensive donor deferrals on the adequacy of the blood supply and to arrive at a policy decision. Some argue that the magnitude of risk does not justify the stringency of the donor deferral policy, given the small risk in a country that was not BSE-endemic or lacked any BSE-contaminated materials in their food supply, but the process was the first to attempt to balance risk with adequacy. Subsequently, vCJD was shown to be transfusion transmissible.[35]

While screening donors for a risk such as vCJD does not have a large negative impact on availability of donations because of its distant impact on most US blood donors, universal screening for other disease agents is not feasible or warranted. For example, screening all donations for *T.* and Zika virus based on geographic exposure or theoretic local exposure can cause significant reduction in the number of collections without adding much value. Universal donation screening for *T. cruzi* antibodies has been replaced with one-time testing with the assumption that a negative test remains consistent throughout the donor's life.[36] Zika screening was challenging as regions of the United States became endemic for the disease after its introduction during the pandemic in 2015 to 2016. Following the pandemic, Zika virus testing (by NAT) was reduced from universal individual donation testing to minipool NAT using a model very similar to that used for WNV.[37,38]

Hemovigilance programs, such as the Serious Hazards of Transfusion (SHOT) in the United Kingdom and others in Canada, France, and a smaller program in the United States, have emerged, supplying evidence about a much broader range of transfusion hazards than just infections.[39] For example, a data-driven decision to minimize plasma transfusions from potentially alloimmunized female donors resulted in a dramatic reduction in transfusion-related acute lung injury (TRALI) in the United Kingdom, and studies in the United States have reproduced this finding. These systems provide an opportunity for monitoring the risks and benefits of new initiatives, (e.g., proactive pathogen-reduction). Pathogen-reduction processes (see box on Pathogen Reduction) offer the opportunity to abrogate most of the residual risk for all of the historically important transfusion-transmitted viral infections, bacterial contamination of platelets, babesiosis and malaria contaminated red cells, WNV infections, and Chagas disease. Pathogen-reduction could eliminate the often lengthy, reactive, iterative paradigm of emergence of a new pathogen in the population, recognition of a material threat to transfusion recipients, development of donor-deferral strategies followed by development and refinement of test systems that has characterized our historical approach. Critically, broadly active pathogen-reduction processes offer a layer of protection against unsuspected emergence of new agents.[40] If already in use, they would need only to be validated as active against a new agent or appropriate model agents. The challenge with this approach is broad-based availability (all components) and wide-scale acceptance, the impact on product quality, and the potential long-term toxicities that may not be apparent in premarketing clinical trials or implementation to date.[41–43]

More recently, as cost pressures for health care increase, transfusion professionals are questioning whether the zero-risk paradigm remains relevant. A consensus conference held in Toronto in October 2010 addressed concerns about "safety at any cost" and inconsistent decision-making practices affecting the blood supply. This initiative has led to a definitive effort to establish a framework for risk-based decision-making under the direction of the Alliance of Blood Operators (www.allianceofbloodoperators.org/abo-resources/risk-based-decision-making/rbdm-framework.aspx). The process involves risk identification, risk assessment, risk management, and risk communication, along with an assessment of risk tolerance, in the context of full and open communication with stakeholders.[44] Risk will never be zero, and there is now a realization that cost considerations,[45] politics, ideology, and public opinion cannot be ignored.

The deferral, notification, and counseling of healthy blood donors after a repeatedly reactive screening test for HTLVs has been problematic, and tens of thousands have been affected since screening started. The vast majority of such tests are false positive; a licensed confirmatory test is now available and will greatly improve this situation.

HUMAN HERPESVIRUS INFECTIONS

Human herpesviruses (HHVs) are enveloped, structurally complex double-stranded DNA viruses that cause common infectious diseases. Primary infection is followed by lifelong carrier states and the possibility of reactivation. They are classified in three subfamilies, *Alphaherpesvirinae, Betaherpesvirinae*, and *Gammaherpesvirinae*, of which the latter two contain the herpesviruses that are of greatest concern from a transfusion medicine standpoint. Members of the *Alphaherpesvirinae* subfamily, herpes simplex viruses (HSVs) and varicella-zoster virus (VZV), are rarely, if ever, associated with transfusion-transmitted infections. Transfusion-transmitted cytomegalovirus (CMV) is well recognized. Transmissions of Epstein-Barr virus (EBV) and HHVs 6 to 8 by blood are virtually nonexistent in the United States because of the use of primarily leukocyte-depleted (leukoreduced) blood products.

Cytomegalovirus

CMV, a beta herpesvirus, infects a wide range of cell types, including leukocytes of the monocyte-macrophage lineage and their progenitors. In the United States, in the population-based National Health and Nutrition Examination Survey (NHANES) III study, 58.9% of individuals more than 5 years old were seropositive, indicating prior CMV infection. Prevalence increases with age and is dependent on race/ethnicity and other demographic factors. The prevention of transfusion-transmitted CMV infection has depended on the use of "CMV safe" blood including a combination of leukoreduced and CMV-seronegative blood. There is, however, some evidence that acute infection may result in plasma viremia and thus the potential for transfusion infectivity.

Primary CMV infection in immunocompetent individuals is usually community acquired, often asymptomatic or associated with a mild, self-limited infectious mononucleosis syndrome. After virtually all infections, latent virus persists permanently in cellular reservoirs, allowing lifelong reactivation, and in the setting of transfusion or transplantation, the potential for viral transmission via non-leukoreduced cellular blood products, and allografts.

In immunosuppressed patients, CMV infection can cause severe morbidity and mortality from pneumonitis, hepatitis, gastroenteritis,

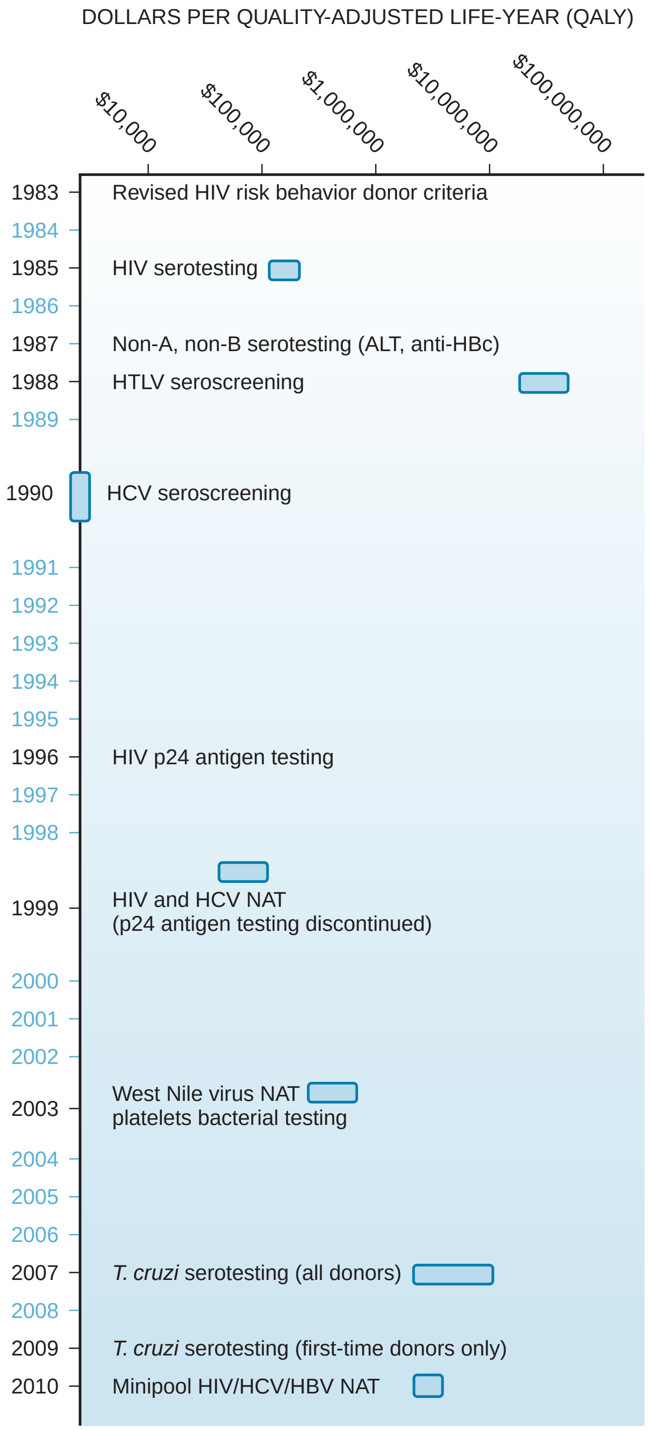

Figure 118.1 VARIOUS SAFETY MEASURES INTRODUCED DURING THE PAST THREE DECADES OF ENHANCED TRANSFUSION SAFETY. The X-axis displays costs associated with these advances per quality-adjusted life-year. Hepatitis C virus seroscreening saves costs. Estimates for platelet bacterial culturing and human immunodeficiency virus p24 antigen testing are not available. *ALT*, Alanine aminotransferase; *anti-HBc*, antibodies against HBcAg; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *HTLV*, human T-lymphotropic virus; *NAT*, nucleic acid testing; *QALY*, quality-adjusted life-year; *T. cruzi*, *Trypanosoma cruzi*.

retinitis, and other inflammatory conditions. CMV infection in low-birth-weight infants is associated with sepsis-like syndromes, respiratory distress, and liver and bone marrow dysfunction. Their infections can be acquired in utero, from breast milk, or from transfusion. Reported infant morbidity varies considerably but can approach 50% of seronegative low-birth-weight infants receiving unscreened, non-leukoreduced blood. CMV-seronegative marrow transplant patients are also susceptible to CMV infection, but the adoption of routine monitoring for CMV antigen or nucleic acid in transplant recipients and of preemptive antiviral therapy have decreased this risk (Chapters 94 and 110). Seronegative solid organ transplant recipients are also susceptible to symptomatic transfusion-transmitted CMV infections. CMV-seronegative, HIV-infected patients are another group at risk for transfusion-transmitted primary CMV infection. The historical risk for CMV infection in immunosuppressed recipients receiving CMV-unscreened, non-leukoreduced blood components varies from 13.5% to 53.3%. The residual risk for CMV infection in seronegative, immunocompetent patients who receive non-leukoreduced cellular blood components unscreened for presence of CMV antibodies is approximately 1%. CMV transmission strictly attributable to blood is rare to nonexistent with the combination of leukoreduction and CMV antibody screening. CMV antibody screening will be replaced by pathogen-reduction methods in the future.

Current practice in the United States is diverse. In a meta-analysis of 11 controlled trials in allogeneic marrow transplantation recipients, 12 of 829 recipients of seronegative units versus 24 of 878 receiving leukoreduced but unscreened units developed CMV infections.[47] Pooling of data from three studies of seronegative or leukoreduced components, in comparison with CMV unscreened components, demonstrated statistically identical 93.1% and 92.3% reduced risks of CMV infection, respectively. Thus, most clinicians consider leukoreduction and CMV seronegative blood to be equivalent; however, clinicians caring for neonates are more likely to require serologic screening. American Association of Blood Banks (AABB) recommends that each institution review its internal policies for blood use in patients vulnerable to CMV infection. The failure of clinicians to recognize recipients requiring CMV-safe transfusion and to request such components is an argument that has been advanced in support of universal pre-storage (versus bedside) leukoreduction.

CMV DNA blood donation screening by NAT may be considered an additional risk reduction measure for donors with seronegative window-period infections. However, current NAT assays would be expected to be equivalent to serologic screening in detecting latently infected blood donors. Any consideration of additional testing is complicated by the absence of randomized studies using contemporary leukoreduction methods and by our lack of understanding of the clinical impact of transfusion-transmitted CMV in an era of CMV monitoring and treatment. But with the advent of pathogen-reduction measures the need for any CMV donor screening will become obsolete. To this end, the Canadian National Advisory Committee on Blood and Blood Products released a consensus statement that leukoreduced products are equally safe as CMV-negative products in all populations except for intrauterine transfusion. Along with this statement, the Committee recommended discontinuing widespread CMV antibody testing and instead for hospitals to maintain a small inventory only for use in this special transfusion scenario.[48]

EPSTEIN-BARR VIRUS (HHV-4)

EBV, a gamma herpesvirus, is the causative agent of heterophile antibody-positive infectious mononucleosis and is etiologically associated with Burkitt lymphoma, nasopharyngeal carcinoma, and post-transplant lymphoproliferative disease (Chapters 59 and 87). Transfusion transmission of the virus is unusual because more than 90% of the adult population is infected, and second infection is prevented by host virus-specific cytotoxic T-lymphocytes, capable of lysing EBV-infected B lymphocytes when viral peptides are expressed on the lymphocyte surface. Rare cases of transfusion-transmitted EBV presenting as infectious mononucleosis have been described in immunocompetent recipients and in immunosuppressed patients following solid organ transplantation. Aggressive EBV-associated lymphoproliferative disorders have been observed in patients with immune injury after cord blood stem cell transplantation but have not been documented following transfusion. B lymphocytes are the likely source of transfusion-transmitted EBV infection, so leukoreduction is an attractive strategy to prevent infection in transfusion recipients. Nonclinical studies suggest that leukoreduction is capable of removing detectable EBV DNA from platelet concentrates and RBCs.

Human Herpesvirus-8

HHV8 is a gamma herpesvirus causally linked to Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman disease (Chapter 88). It is highly cell-associated with lymphocytes and monocyte-macrophages. Although generally spread person to person, including sexually,[49] it has been shown to be transmitted by transplantation. There is convincing evidence of HHV8 transmission by transfusion in sub-Saharan Africa, where the seroprevalence of HHV8 among blood donors is 40%, and fresh, non-leukoreduced blood transfusions are commonly used. The seroprevalence of HHV8 among US blood donors has been reported to be as high as 20% to 25%, but a multicenter study using well-characterized antibody tests on donations from five representative US regions estimated a seroprevalence of only 3.5% and showed no evidence of viremia by PCR. The possibility has been raised that transfusions in the United States have transmitted HHV8, but subsequently reported studies comparing transfused patients with un-transfused controls are not suggestive. Similar to what has been established for CMV infection, it is assumed that widespread leukoreduction in the United States mitigates the risk for HHV8 transmission by transfusion, but this has not been proven.

Other Herpesviruses (Herpes Simplex, Varicella-Zoster Virus, Human Herpesviruses 6 and 7)

Infection with these viruses is very common to ubiquitous. From 50% to 80% of the adult population is seroreactive to HSV-1 and/or HSV-2, up to 95% for VZV, more than 90% for HHV-6, and 70% to 90% for HHV-7. Primary infection is followed by lifelong latency for all HHVs, and reactivation from latency is described for all. There is no credible evidence of transfusion transmission of HSVs (causing orolabial and genital herpes and herpes encephalitis), VZV (chickenpox and shingles), or HHV-6 or HHV-7 (exanthem subitum or roseola infantum, multiorgan dissemination with reactivation in immunocompromised hosts).

Viremia occurs during both primary and reactivation infection with HSV and VZV, but transmission by blood has never been reported for these viruses. Although the lymphocyte association of HHV-6 and HHV-7, like CMV and EBV, suggests the possibility of transfusion transmission, well-documented case reports or series are not available. Case reports of HHV-6 transmission by hematopoietic stem cells used molecular methods to detect integrated donor HHV-6 DNA in engrafted donor cells and appear to represent transmission of latently infected cells rather than of active infection. Furthermore, transplant recipients may reactivate preexisting latent infection, thereby confounding the evaluation of potential transfusion transmission. HHV-6 and HHV-7 are highly leukocyte associated after primary infection, and leukoreduction would be expected to be effective by analogy to human CMV; however, cell-free viremia can be found during primary infection.

PARVOVIRUS

Human parvovirus B19 (erythrovirus) is a 19- to 23-nm–diameter nonenveloped, single-stranded DNA virus from the family *Parvoviridae*, as are adeno-associated viruses, human parvovirus 4 (PARV4), PARV5, and bocaviruses. B19 has at least three genotypes (Chapter 33). Genotype 1 infections appear predominantly in the United States and Europe. Genotype 2 infections appear confined to those born before 1973, and genotypes 3a and 3b infections occur in parts of West Africa. Infection with B19 is ubiquitous, with 50% of high school children demonstrating seropositivity, increasing to 90% in older adults. Approximately three-quarters of transfusion recipients have B19 IgG antibodies. Natural transmission occurs through the respiratory route most commonly and transplacentally to the fetus in up to 30% of women infected during pregnancy. Transfusion of blood and blood components, plasma derivatives, and organ transplantation are minor routes. In women infected during weeks 9 to 20 of pregnancy, fetal death occurs in 10% to 15% from hydrops fetalis. The low observed incidence of infection in transfusion recipients results from prior infection and immunity, co-infusion of neutralizing antibodies, and possibly because very high viral loads are uncommon in donor blood.

Parvovirus B19 causes erythema infectiosum, or fifth disease, oligoarthritis, and neurologic and myocardial infections. Following acute infection, viral replication leads to extremely high-titer viremia that declines at the time of IgM seroconversion approximately 9 days following infection. B19 may persist in bone marrow, liver, tonsils, and skin of healthy persons with no recognized clinical significance, and low levels of B19 DNA have been amplified from the blood of healthy people for several years after primary infection. The virus is highly tropic for erythroid progenitor cells using the P-blood group antigen, or globoside, as its receptor, causing aplastic crises in patients with sickle cell anemia, other inherited hemolytic diseases, and conditions associated with decreased RBC survival, malaria, and HIV/AIDS. Acute infection impairs erythropoiesis for 7 to 10 days, with complete cessation for 3 to 7 days, resulting in hemoglobin decreases (Chapter 33). Persistent infection, causing red cell aplasia, occurs in those who fail to develop neutralizing antibodies to the viral capsid protein 1. In these patients, the virus continues to circulate at high titer, greater than 10^{12} International Units (IU) or equivalent genome copies per mL. Patients at risk for persistent infection include those receiving chemotherapy and immunosuppression, organ transplant recipients, and those with HIV. Infection in these groups tends to respond favorably to intravenous immunoglobulin infusions.

B19 virus–impaired erythropoiesis appears to be multifactorial. B19 viral nonstructural protein 1 (NS1) mediates apoptosis via an 11-kDa protein that perturbs signal transduction and induces apoptosis. B19 viral DNA activates Toll-like receptor 9 inhibiting cell growth and is toxic for infected cells.

Blood and plasma-derivative transmission involves donations during the transient 1- to 2-week high-titer viremic period. The prevalence of B19 viremia has been reported as 0.003% to 0.84% in blood and plasma donors. In a study involving more than 12,100 B19 DNA–tested blood donations, given to surgical patients with a 78% pretransfusion B19 IgG seroprevalence, no B19 transmissions occurred from transfusions containing less than 10^6 IU per mL.[50] Hence most blood transfusion recipients are believed to be at low risk for an infectious exposure. However, careful studies in Japan have demonstrated some transmissions from components with comparatively low viral loads of around 10^5 IU per mL).[51,52]

By contrast, recipients of plasma-derived products made from manufacturing pools of thousands of donations have a significant risk because the virus survives partitioning, ethanol fractionation, and other anti-infective measures applied to derivatives, and a single high-titer viremic donation can overcome the neutralizing activity of antibody in the pool. Recipients of coagulation concentrates are at highest risk, whereas those of intravenous immunoglobulins and albumin are less so based on cohort studies of prevalence. In one report, 14% of viremic plasma donors had titers between 10^4 and 10^7 IU per mL, and one in 13,000 had titers greater than 10^7. In observational studies, seroconversion occurred among recipients of plasma derivatives with high titers, $10^{7.5}$ to $10^{8.5}$ IU per mL, treated with the solvent/detergent pathogen-reduction technique, suggesting that the protective effect of neutralizing anti-B19 antibodies is exceeded in the presence of high viral loads (see box on Pathogen Reduction). Since B19 is a nonenveloped virus, solvent/detergent pathogen-reduction treatment is ineffective in preventing B19 transmission in hemophilia patients receiving factor concentrates. Freeze-drying and dry-heat treatment (80°C [176°F] for 72 hours) inactivate more than 4.7 logs B19, but this is not always sufficient to prevent transmission.

PATHOGEN REDUCTION

Pathogen-reduction technology (PRT) offers a proactive strategy to address new threats; these technologies involve physical, chemical, and photochemical treatments of blood components to inactivate or decrease viral, bacterial, and parasite infectivity.[40,42]

Beginning in the 1980s, heat treatment, nanofiltration, and solvent/detergent treatment eliminated or reduced viral transmission in products derived from large-scale plasma fractionation such as albumin, immunoglobulin, and hemostatic factor concentrates.

In the past two decades, attention turned to whole blood–derived components: frozen plasma, platelets, and red cells. For these, PRT utilizes solvent-detergent, UV and methylene blue and visible light treatment for plasma; amotosalen (psoralen) and UVA light, and riboflavin (vitamin B_2) and UVB and UVA light for plasma and platelets; and riboflavin/UV light and S303 (a labile alkylating compound) for whole blood or red cells. Many European countries use PRT for platelets and plasma. Amotosalen/UVA-treated plasma and platelets (Intercept, Cerus Corporation) and solvent-detergent plasma (Octaplas, Octapharma) are FDA-approved and available in the United States. Because solvent-detergent does not inactivate nonenveloped viruses, Octapharma screens all incoming units in pools to prevent the introduction of HAV, HEV, and B19. Breakthrough HEV infections have been described with Intercept-treated plasma in France.[22]

Amotosalen/UVA (Intercept, Cerus) and riboflavin/UV (Terumo BCT) have been investigated to the greatest degree in North America. They provide significant antiviral activity against all agents for which tests are performed currently, human immunodeficiency virus (HIV), hepatitis B and C viruses (HBV and HCV), human T-lymphotropic virus (HTLV), West Nile virus (WNV), the parasite *Trypanosoma cruzi*, and cytomegalovirus, but the two methods appear to differ in their inactivation capacity. PRT also inactivates agents causing bacterial contamination of platelets; inactivates white blood cells to prevent transfusion-associated graft-versus-host disease; decreases formation and release of cytokines during storage, reducing febrile, nonhemolytic transfusion reactions; and abrogates white blood cell–induced alloantibody (e.g., human leukocyte antigen [HLA] antibody) formation mitigating alloimmune platelet refractoriness. Intercept-treated plasma (as mentioned) and platelets are FDA approved and available in the United States; clinical studies on pathogen-inactivated red cells (Cerus) and whole blood (Terumo BCT) are ongoing.

Methylene blue and visible light inactivate pathogens in plasma by targeting nucleic acids. However, this alters fibrinogen structure. Because it damages cell membranes, methylene blue is not used for platelets or red cells. It is not effective against hepatitis A or parvovirus and is not recommend for use in the treatment of thrombotic thrombocytopenic purpura.

Amotosalen/UVA targets nucleic acids. Platelets treated with these technologies have somewhat lower 1-hour post-transfusion corrected-count counts.[43] In clinical trials, mild and moderate bleeding frequency is increased, but not severe bleeding complications; the time between transfusions and the total number of platelet transfusions have not generally been different. Pulmonary toxicity similar to transfusion-related acute lung injury (TRALI) has been reported in clinical trials and in animal model experiments in which UV light has been implicated. Previous clinical trials in red blood cells (RBCs) were halted because of asymptomatic immunoreactivity against the red cell neoantigens believed to be the result of treatment and are being resumed with a reformulated process. Preliminary reports suggest riboflavin/UV causes functional impairment in red cells stored nearest the 42-day expiration Although there have been discussions about the potential for adverse reactions to treated products, extensive reviews of European data do not support the additional concern. Nevertheless, initial implementation of the Intercept platelet technology will be accompanied by Phase 4 studies in the United States.

Interest in PRT remains high because it reduces sepsis-related platelet transfusion complications and will eliminate the need for complex testing procedures to reduce bacterial risk related to contaminated platelets; inactivates parasites such as *Babesia microti* and *Plasmodium falciparum;* mitigates risks associated with recognized emerging pathogens such as dengue, chikungunya, and Zika viruses; and proactively decreases threats from unknown, emerging pathogens. It should be noted that inactivation capabilities differ greatly between the various technologies, and each must be evaluated for its intended use.

Currently, plasma derivative manufacturers use “in-process” NAT to identify and remove source (from paid and volunteer donors) and recovered (from volunteer whole blood donors) plasma units with the objective to assure that manufacturing pools have parvovirus B19 DNA titers no greater than 10^4 IU per mL. Approximately 1 per 10,000 plasma units is withheld from further processing. For volunteer whole blood donors, 1 per 6000 to 1 per 16,000 have titers greater than 10^6 IU per mL. Because individual whole-blood donations rarely cause recognized parvovirus infection, testing of single red cell units, platelets, or plasma for transfusion for B19 DNA is not currently required, although some advocate use of B19-tested blood components for those potentially at risk, including pregnant women, neonates, those with reduced RBC survival, and immunocompromised patients.

Of note, PARV4 and PARV5 have been detected in pooled plasma derivative samples, but the clinical significance is not known; limited clinical disease associations have been described.[53]

WEST NILE VIRUS

WNV is a mosquito-borne lipid-enveloped RNA virus in the Japanese encephalitis complex of the family *Flaviviridae*. Transmitted bird-to-bird primarily by culicine mosquito vectors, human infections occur incidentally. The first cases were identified in the West Nile district of Uganda in 1937. Subsequently, outbreaks occurred in the Middle East, South Africa, and Europe. The first North American cases appeared in New York City in 1999. Starting in July 2000, WNV cases spread to the Mid-Atlantic states. This was followed in the next 3 years by transcontinental dissemination. During the summer of 2002, a model suggesting a significant risk for WNV infection in blood donors was published,[54] and then four recipients of organ allografts from a single donor developed neuroinvasive WNV infection. Infection of the organ donor was traced to donor blood transfused before death from trauma. Transfusion transmission was documented in 23 recipients in 2002 against a background of 2946 cases of WNV-meningoencephalitis (WNME).[55] These events provoked a multidisciplinary effort, successfully engaging the transfusion medicine community, the manufacturers of blood donor–screening NAT platforms, and public health officials and regulators to develop and deploy, under an investigational new drug (IND) exemption, high-throughput screening tests in the 10 months before the 2003 transmission season began. WNV test implementation represents the benchmark for responsiveness to a serious emerging transfusion-transmitted infection in the United States.[56,57]

In 2003, 2946 WNME were reported and 714 healthy blood donors tested WNV RNA–positive. In 2004 case reports declined in the Northeast but extended westward into Arizona and Southern California. In 2005 more than 1300 WNME cases were reported, with approximately 25% occurring in California, relatively high activity in South Dakota, Nebraska, Louisiana, and Illinois, and low activity in the Northeast. In 2006 over 400 WNV RNA–positive blood donors were identified. Subsequently WNV activity was reported in Washington State for the first time, and high rates of infection were noted in Idaho, California, Nebraska, Illinois, Louisiana, and the Dakotas. By 2011 fewer than 150 blood donors tested positive with the highest frequencies in New York, Texas, Arizona, and California. The frequency of both WNME cases and RNA-positive blood donors continues to vary by year and remain unpredictable. In total, from 2002 to 2014 nearly 19,000 cases of WNME have been recorded with 4355 RNA-positive blood donors identified, which are related in magnitude by year.[38]

WNV RNA is believed to appear 1 to 3 days after a bite of an infected mosquito. In contrast to HIV and HCV, peak WNV levels are low (maximum observed 720,000 copies/mL, median 3500 copies/mL compared with 10^5 to 10^7 copies for HIV and HCV). In cohort studies of blood donors with positive WNV RNA tests, only 29% to 61% (retrospectively) describe any symptoms before or after donation consistent with WNV infection, compared with 3% to 20% of those not infected, demonstrating that the donor history is neither sensitive nor specific enough to prevent transfusion transmission.[58] Testing for antibodies also will not prevent transmission because IgM antibodies appear a median of 14 days and IgG antibodies a median of 17 days after infection and infectivity disappears rapidly with the development of antibody. These data explain the selection of WNV NAT for the testing strategy. To maximize efficiency, donation samples are tested in minipools containing aliquots from 6 to 16 donors, as is done for HCV, HBV, and HIV.

Despite minipool NAT, six transfusion-associated WNV cases occurred during 2003. The implicated donors were antibody-negative and had low-level RNA that escaped detection in their minipool (i.e., diluted) samples. At the end of 2003 an observation was made, even before the documentation of these transfusion transmissions, that the viral load in some donor samples is too low for detection by minipool NAT. Consequently, strategies have been developed to switch from minipool-NAT to NAT on individual donation aliquots (ID-NAT) in areas experiencing high WNV activity.[59] While ID-NAT year-round is cost prohibitive, its utility is likely to be greatest during WNV "season," that is June through December, in the United States. Alternatively, pathogen reduction would alleviate the residual risk of TT-WNV, thus further enhancing the safety of the blood supply.[60] In total, following the 23 cases of transfusion-transmitted WNV documented before the initiation of donation NAT screening, an additional 14 have been reported, most related to donations having only low levels of RNA; the last was in 2016. All implicated donations, except one in 2002, have been IgM negative. Blood centers must remain vigilant for appropriate conversion to individual donation-NAT for this strategy to be effective. A drawback of detecting RNA-reactive donations is that they are a lagging indicator and not an early warning system such as mosquito and bird activity, particularly during the onset of an epidemic period.[37]

DENGUE VIRUSES

This mosquito-borne infection is of great interest as an emerging pathogen with the potential to spread by transfusion. Forty percent of the world's population lives in areas with risk for dengue, including many areas visited by US travelers. It has spread rapidly in Latin America and the Caribbean since the 1980s. Dengue is endemic in Puerto Rico, the US Virgin Islands, and American Samoa, and there have been outbreaks in Hawaii, Texas, and Florida during the last 10 years. Dengue is caused by four related flaviviruses spread person to person by *Aedes aegypti* and *Aedes albopictus*, which are present in 16 and 35 US states, respectively. Over 2.3 million dengue clinical cases occurred in the Americas during 2015.

Most infections are asymptomatic, but illness ranges from undifferentiated fever to classic break-bone fever and severe dengue (dengue hemorrhagic fever and dengue shock syndrome). An approximately 7-day viremia is a feature of both asymptomatic and symptomatic infection, and asymptomatic blood donors from Hong Kong, Singapore, Brazil, and Puerto Rico have transmitted dengue to blood recipients in seven clusters. Although such reports are limited, compared with the high rates of vector-borne infection, there is no systematic surveillance for transfusion-transmitted dengue and its recognition in the face of widespread outbreaks is problematic.[61] RNA-positive, asymptomatic donors have been identified in Brazil, Central America, and Puerto Rico using NAT and antigen detection tests. Rates of donor RNA positivity in Puerto Rico are comparable to those found in US donors during the most active WNV seasons.[62,63] A recent study in Brazil documented transfusion transmission; however, when patient charts of those donors who received an RNA-positive unit and were shown to be infected were compared with control recipients who did not receive an RNA-positive unit, there was no reported increase in clinical illness.[64] This further illustrates the difficulty in identifying transfusion-transmitted dengue among severely ill patients who are frequently transfused.[63]

In the absence of significant outbreaks of locally-transmitted dengue in the continental United States, transfusion risk relates mainly to return of infected, asymptomatic or pre-symptomatic travelers to the United States from endemic areas. A 3- to 14-day incubation period precedes symptom onset. Deferral for travel to malarious areas (1 year for a US resident) offers some protection, but a large proportion of dengue-affected areas frequently visited from the United States are malaria-free and donor-travelers to those areas could potentially introduce the virus into the community and the blood supply. Careful surveillance and a high index of suspicion when sustained febrile illness occurs following transfusion are required to recognize transfusion-related dengue. Preliminary data on travelers from the United States to dengue-endemic destinations that are malaria-free suggest that 2- to 4-week deferral for travel to dengue-affected areas may have a greater adverse impact on blood donation than current malaria deferrals. To date, however, there are no instances of transfusion-transmitted dengue in the continental United States that are attributable to donor exposure through travel. The conditions for sustained spread of dengue exist in large areas of the United States: a source of infection from travelers and immigrants; a susceptible population; and competent vectors. Whether the recently identified outbreaks in the United States will continue or increase, and whether sustained transmission will begin is unknown. Transfusion-transmitted dengue has been identified by one group as one of the three highest-priority emerging infections posing a potential threat to transfusion recipients in the United States and Canada and has been the subject of discussions at the FDA's Blood Products Advisory Committee (see boxes on Emerging Infections and Xenotropic Murine Leukemia Virus–Related Virus: A Lesson Learned).

EMERGING INFECTIONS

The experiences with human immunodeficiency virus (HIV), new variant Creutzfeldt-Jakob disease (vCJD), and West Nile virus (WNV) have made it clear that planning for the emergence of new pathogens that may threaten the blood supply is critical in order to shorten the interval from emergence to mitigation. To that end, the characteristics of pathogens likely to enter the blood supply must be understood. These include the ability of the agent to establish an asymptomatic blood-borne phase, to survive under contemporary processing and storage conditions, to establish infection by the intravenous route, and to cause significant morbidity in a transfusion recipient.

Using these characteristics and a review of contemporary literature, the Transfusion Transmitted Diseases Committee of the American Association of Blood Banks (AABB), from 2005 to 2009 produced a compendium of infectious agents that might become relevant to transfusion medicine and attempted to prioritize those that were identified.[65] A series of 68 fact sheets was developed. The fact sheets provide transfusion medicine professionals and clinicians with an overview of the agents' phylogeny, epidemiology, clinical characteristics, and interventions that might be useful to protect the safety of the blood supply. Three agents were included in the highest priority stratum: *Babesia* spp., dengue viruses, and the vCJD prion; a section on each is included in this chapter. The fact sheets are freely available online, cover many of the agents discussed in this chapter, and have been updated when required (www.aabb.org/tm/eid/Pages/eidpost-pub.aspx).

Since the original publication, several new monographs have been added, reflecting an ongoing "horizon-scanning" initiative designed to alert the medical community to potential threats. These include yellow fever and the yellow fever vaccine viruses after the latter was transmitted to blood recipients when recent vaccine recipients failed to divulge that information during blood donation. Other fact sheets have been updated and rereleased to capture relevant new information (see box on Xenotropic Murine Leukemia Virus-Related Virus). The availability of these materials to the transfusion medicine and general medical communities is meant to increase awareness that unexpected infections in transfusion recipients should trigger consideration of that source and to provide background allowing the rational consideration of approaches to avert and minimize their spread.[66]

XENOTROPIC MURINE LEUKEMIA VIRUS–RELATED VIRUS: A LESSON LEARNED

The alleged association of the gamma retrovirus xenotropic murine leukemia virus–related virus (XMRV) with chronic fatigue syndrome/myalgic encephalomyelitis (CFS/ME) is paradigmatic of the difficulties inherent in the real-time assessment of potential and emerging transfusion-transmissible infections. A group of CFS/ME patients and controls were evaluated using polymerase chain reaction (PCR), virus isolation, serology, and immunohistochemistry.[67] Evidence of the virus's presence was strongly associated with the clinical diagnosis, culturable virus was found in plasma, and the issue of transfusion transmission was appropriately raised.

Multiple subsequent studies from other groups over the ensuing 2 years failed to confirm the presence of XMRV in a variety of populations. Several publications suggested that PCR contamination underlies some positive results; however, data now indicate that XMRV arose as a recombinant of two murine leukemia viruses during passages in nude mice, leading to the conclusion that the initial findings were an artifact.[68] With these findings, the original publication was retracted. The absence of transfusion transmission and of the agent were also demonstrated in studies on the donor pool.[69] The amount of research and resulting publications on this recombinant laboratory-generated virus were simply another lesson in caution that is required prior to claims of a viral agent being a human pathogen, or in this case, being the result of recombinant contamination.

CHIKUNGUNYA VIRUS

Chikungunya virus is another tropical arbovirus transmitted by *Aedes* spp. mosquitoes. It is a togavirus of the alphavirus group and, although first recognized in Africa has been notably responsible for explosive outbreaks in the islands of the Indian Ocean and has most recently spread to the Caribbean, where more than 1.7 million clinical cases were reported from the end of 2013 to the middle of 2015, including RNA positivity in blood donors.[70] Although there have been no reported cases of transmission by transfusion, the similarity of early infection to that of dengue has resulted in significant concern. Notably, French authorities responded to the outbreak in La Réunion by halting local collection of red cells (providing for the island's needs by supplying blood from the French mainland) and by implementation of limited NAT and the use of pathogen reduction for platelets.[71] Other precautions that have been used have been to strengthen requirements of post-donation information from donors (a process that is enhanced by the high [50% to 80%] frequency of symptoms among infected subjects), along with deferrals for residence in affected areas. Chikungunya symptoms are similar to those of dengue, but without the impact upon the circulatory system. Arthralgia is, however, a prominent symptom and may be prolonged. Routine testing is not currently available.

ZIKA VIRUS

Zika virus is another tropical arbovirus of the flavivirus group. Again, first recognized in Africa, it has been circulating in the Pacific islands at relatively modest levels. In 2007 the first human outbreak was recognized on the island of Yap in Micronesia with subsequent spread in 2013 to French Polynesia.[72] Testing performed in Polynesia showed 2.8% of presenting donors to have Zika virus RNA. Within 2015 Zika virus and associated disease emerged in Brazil and began spreading beyond other South and Central American countries, Mexico, and the Caribbean including travel-associated cases in the United States.[73] By early 2016, the World Health Organization declared the Zika outbreak a Public Health Emergency of International Concern to increase surveillance and vector control and to expedite the development of diagnostics, treatment, and vaccine development. Given the similarity to and relationship with dengue, there are concerns about the spread of Zika virus and local transmission in the continental United States. At the height of the Zika epidemic in 2016, the number of cases within the US reached over 5100 and cases within US territories numbered over 36,500.[74] A particular concern is that infection in pregnant women is associated with an unexpectedly high and troubling incidence of microcephaly and other developmental abnormalities in fetuses.[75,76] Unlike the other mosquito-borne viruses, Zika appears to be sexually transmitted (and can be recovered from urine and semen).[77] Other than mosquito transmission, like dengue, transfusion transmission has been reported. As a result, the US FDA implemented universal, individual donation NAT for Zika virus RNA in 2016. The guidance was updated in July 2018 to allow for minipool NAT until certain triggers are met for individual testing based on regional virus activity or unless pathogen reduction technologies are used.[78]

SARS-COV-2 (COVID-19)

In late 2019, a novel coronavirus, SARS-CoV-2, was identified in the Wuhan province of China (Chapter 153). The disease associated with the virus (coronavirus disease 2019; COVID-19) ranges from asymptomatic to severe infection and has spread rapidly throughout the entire world, causing over 243 million cases of COVID-19 and over 5.0 million deaths, as of the time of writing, in an ongoing pandemic. Reports have shown detection of RNA in blood products,[79] however no evidence of transmissibility of SARS-CoV-2 through blood transfusion has been seen.[80,81] Despite this, the transfusion medicine community has remained vigilant of the ongoing developments and mutations of the virus, its associated disease, and potential blood product therapies. Antibody screening of all donations has been approved by the FDA to determine if a blood donor has had an antibody response to SARS-CoV-2 exposure, with many large blood collection organizations providing antibody-positive blood products to hospitals to treat patients with convalescent plasma, currently approved through EUA. Seroprevalence studies show a range of the US population with detectible antibodies from 1% to 23% in the general population and in 1.82% in the blood donor population.[82,83]

PANDEMIC INFLUENZA A

There was interest in the transfusion safety implications of influenza A even before the swine origin A-H1N1 pandemic of 2009 to 2010.[84] Viremia in donors, and the potential for infection of recipients, were discussed during meetings of an AABB pandemic influenza planning task force as early as 2008, based on old literature demonstrating the virus in the blood of experimentally infected volunteers and case reports of viral dissemination during human infection with highly pathogenic avian A-H5N1 virus. Subsequent studies have failed to identify influenza viruses in donors drawn in US communities during periods of high seasonal influenza activity or in donors with the onset of influenza-like illness immediately following donations.[85] The current consensus is that pandemic influenza is not likely a threat to blood recipients, but that disruption of the blood supply in a severe pandemic is a more important possibility, requiring careful advance planning.

BACTERIAL INFECTIONS

Cellular Product Contamination

Bacterial contamination of red cell and platelet components occurs primarily as a result of the inability to achieve complete skin disinfection at the donor phlebotomy site, where bacterial populations survive in skin appendages below the accessible surface and contaminate skin plugs made by the phlebotomy needle and enter the blood bag. Transient asymptomatic bacteremia at the time of blood donation, a break in technique during pooling the contents of or sealing blood containers, disruption of blood bag integrity or its contamination during manufacturing are other rare sources. Bacterial proliferation occurs more rapidly in platelet concentrates stored at room temperature than in red cells maintained at 4°C (39.2°F). As such, the FDA published updated recommendations in December 2020 to control the risk of bacterial contamination of products stored at room temperature.[86]

The rate of bacterial contamination in allogeneic platelets was estimated at 1 per 1000 to 3000 units with life-threatening septic reactions occurring in one per 15,000 to 100,000 recipients before routine implementation of culture-based tests to detect bacteria in apheresis platelets in 2004. These tests reduced contamination rates to approximately 1 per 5000 to 8500 platelet units. Septic reactions occur in approximately 30% of recipients receiving contaminated platelets. Bacterial contamination was responsible for 6 of 50 (12%) of transfusion-related deaths reported to the FDA in FY2018.[87] Prior years, including the period between 2014 and 2017, saw a smaller percentage of fatalities due to contamination of products, however, there is consensus that transfusion reactions are badly under recognized and under reported. Culturing fails to detect 50% to 75% of contaminated units. This undetected contamination occurs primarily when minimal bacterial levels are present when cultures are obtained, yielding culture aliquots without bacteria. Subsequently the few bacteria remaining in the blood bag can presumably grow out during storage, producing transfusions with significant bacterial levels. To minimize this, collection facilities generally hold apheresis platelets for approximately 24 hours after collection before sampling to allow low bacterial inocula to proliferate, improving the sensitivity of culture. As mentioned, improved skin antisepsis and diversion for laboratory testing of the first 40 mL of blood, which contains the skin plug, provide further reduction of contamination rates, transfusion reactions, and fatality rates by lowering the bacterial load that otherwise would enter the final component container.

Septic transfusion reactions should be suspected when one or more of the following occur within 1 to 4 hours of transfusion: temperature elevations greater than 1°C to 2°C (1.8°F to 3.6°F), chills and rigors, tachycardia more than 120 beats/min or an increase of 40 beats/min, or an increase or fall in systolic blood pressure of greater than 30 mm Hg. Additional signs and symptoms can include nausea, vomiting, diarrhea, bleeding, oliguria, or septic shock. Septic transfusion reactions may be confused with hemolytic transfusion reactions, febrile, nonhemolytic transfusion reactions, or TRALI.

Platelet concentrates contaminated with *Staphylococcus aureus*, *Serratia marcescens*, *Staphylococcus epidermidis*, *Escherichia coli*, and *Streptococcus* species account for most clinically recognizable reactions. *Propionibacterium acnes* is a frequent culture isolate from platelets during storage when an anaerobic culture is also performed but is not believed to be responsible for a significant number of reactions. A clinically relevant case of *Clostridium perfringens*, another anaerobe, has been reported.[61] The bacterial dose in platelet concentrates and species virulence correlate with the clinical outcome. Bacterial concentrations greater than 10^5 colony-forming units (CFU)/mL are more likely to result in severe reactions or fatalities. Alternatively, low concentrations, 10^4 or fewer CFU/mL of skin organisms, frequently do not elicit reactions. Endotoxin elaboration by gram-negative organisms is associated with the most severe reactions, but the vast majority of gram-negative organisms are easily detected by bacterial culture.

In addition, bacteria grow at variable rates. *S. epidermidis* grows slowly, and *P. acnes* requires on average 3 days for detection. Because collection agencies continue bacterial culturing until the platelet unit expiration date or detection of growth, there is further opportunity to intercept released platelets that have not been transfused and to alert physicians about the potential risk for bacterial contamination in cases where the units have been administered. However, the vast majority of septic reactions are associated with false-negative culture tests because of sampling limitations as noted earlier. The overall rate of bacterial contaminated apheresis platelets is 1 per 5000 and for septic transfusion reactions is 1 per 107,000 distributed components.[88]

Before the mid-1980s, platelet concentrates were stored for 7 days. Following reports of septic reactions, the shelf life was reduced to 5 days to decrease the interval during which bacteria could proliferate. In the United States, blood suppliers distributed platelets from 2005 to 2008 with a 7-day shelf life following enrollment in an FDA-mandated post-market surveillance study (Post Approval Surveillance Study of Platelet Outcomes, Release Tested [PASSPORT]) that included testing for bacterial contamination by a sensitive culture method. Initial experience suggested that extended platelet storage coupled with bacterial testing substantially decreased platelet loss from outdating. However, the PASSPORT study found 1 per 4329 tested platelet products with negative bacterial cultures had bacterial growth when tested at the end of storage, 7 days later.[89] Septic transfusion reactions occurred in approximately 1 per 25,000 platelet transfusions, some following infusion of 3-day stored platelets, most with those stored 4 days or longer, leading to reinstatement of the 5-day platelet shelf life. A recent report of a cluster of four *Acinetobacter calcoaceticus/baumannii* complex septic transfusion reactions involving apheresis platelets includes one that occurred following pathogen reduction. Co-component sterility, successful inactivation of the cultured isolate, detection of photoproduct residuals in the treated platelets, and failure to amplify mitochondrial DNA in the treated platelets all suggest successful pathogen reduction. Unidentified environmental sources and inherent or acquired bag defects may have contributed to bacterial contamination following successful pathogen reduction.[90] Of significance, each of the four septic transfusion reactions that were part of this cluster were caused by genetically related strains of *Acinetobacter*, none of which implicated the apheresis platelets.[91] Several additional bacterial mitigation methods were used for the platelets in this case cluster demonstrating that even with the most stringent mitigations, risk still occurs. Additional mitigations included aerobic and anaerobic culture (one case), point-of-issue testing (two cases), and pathogen reduction (one case).

Alternative methods for detecting bacterial contamination include point-of-release testing in the hospital transfusion service. Considered a supplement to culture-based testing, this assay can be used shortly before issuing platelets for transfusion to detect units missed by early culture. This rapid qualitative immunoassay tests for the presence of conserved bacterial antigens (gram-negative lipopolysaccharide and gram-positive lipoteichoic acid). In one report using this test, 1 per 3000 platelet doses contained gram-positive organisms when issued 3 or more days after collection.[92] Other methods, under development for mitigating septic platelet events, include microcolorimetry, bacterial spore biosensors, real-time PCR, flow cytometry, and detection of other bacterial cell wall constituents. Pathogen-reduction technology using licensed psoralens (Intercept) or riboflavin plus UV light provides an opportunity for inactivating multiple pathogens before they can proliferate. Not all technologies, however, inactivate different bacterial isolates with the same efficiency.

RBC bacterial contamination rates approximate 1 per 30,000 units with adverse clinical outcomes occurring in 1 per 500,000 transfusions and fatalities occurring at a rate of 1 per 10 million. Most septic reactions occur in units stored for 4 weeks or longer, reflecting the delayed growth of bacteria at 4°C (39.2°F).

Bacteria isolated from contaminated red cell units include *S. marcescens*, *E. coli*, *Pseudomonas* species (especially *Pseudomonas fluorescens*), and *Yersinia enterocolitica*. The latter two are psychrophilic and known to proliferate in the cold. Gram-positive skin saprophytes account for most of the organism-contaminating platelet concentrates, with the remaining attributed to gram-negative organisms associated with occult bacteremia.

Immediate recognition of a platelet or red cell septic reaction and immediate discontinuation of the transfusion, supportive care, and antibiotic administration are the mainstays of therapy. Prevention relies on careful donor selection and scrupulous adherence to aseptic techniques and precautions from component collection, processing, transport, and storage to transfusion at the bedside. The Gram stain reveals bacteria in platelet concentrates contaminated with more than 10^5 to 10^6 CFU/mL.

A proportion of donors of platelet units contaminated with *Streptococcus bovis* or *Streptococcus infantarius* have been found to have colonic polyps or colon cancer.

SPIROCHETE INFECTIONS

Syphilis

US blood banks first screened donors with a serologic test for syphilis in 1938, and screening has been a regulatory requirement since 1958. It was the first test mandated for US donors and stood alone before the discovery of the Australia antigen for hepatitis almost two decades later. More than 100 transfusion syphilis cases were published before World War II, and many more certainly occurred. The last alleged case of transfusion-transmitted syphilis in the United States, however, was in 1966. Since then, hundreds of millions of components have been transfused in this country without another recognized case. There are multiple explanations for the disappearance of transfusion-transmitted syphilis in addition to improvements in testing: (1) the dramatic decline in the incidence of early syphilis in the United States over the decades, more than an order of magnitude, reducing the reservoir of donors able to transmit; (2) the end of direct donor-to-recipient transfusion combined with the loss of viability of *Treponema pallidum* in stored blood—the latter attributed to poor survival in refrigerated RBCs and to the high oxygen tension in platelets stored at higher temperatures; (3) the ubiquitous administration of antibiotics for trivial to serious viral, bacterial, and noninfectious clinical syndromes, especially to those sick enough to be transfused; (4) donor deferral for behavioral correlates of syphilis risk (e.g., male sex with males, occurrence of recent sexually transmitted infection in donors, exchange of drugs or money for sex, intravenous drug use); (5) passive surveillance for transfusion-transmitted syphilis compounded by the failure of recognition by physicians (who may have never seen syphilis, venereal or otherwise); and (6) donor illness during spirochetemia severe enough to prevent their presentation to donate blood or causing deferral. The relative contributions of each of these factors are unquantified.

Most blood collection facilities screen donors with an automated test for detecting treponemal antibodies (e.g., *T. pallidum* hemagglutination assay and *T. pallidum* particle agglutination assay); treponemal antibody confirmatory test usually follows using a variety of methods such as enzyme-linked immunosorbent assay (ELISA) or fluorescent treponemal antibody, absorbed (FTA-abs) test; most blood centers further test donors with treponemal antibody reactivity using a nontreponemal test (e.g., rapid plasma reagin [RPR]) to stage the reactivity as recent or past. Approximately 50% of donors with confirmed positive treponemal test results have evidence of a treated syphilis infection. Donations with reactive syphilis tests are generally discarded. Blood centers defer donors with positive treponemal confirmatory tests; donors may be reentered (regardless of their nontreponemal test results) 12 months after completion of treatment for syphilis. Treponemal and nontreponemal false positivity occurs in healthy donors caused by cross-reactivity with a wide variety of infectious diseases other than syphilis, in those with high-titer human leukocyte antigen (HLA) antibodies, after some immunizations, with autoimmune disease and other chronic inflammatory diseases, and have increasing prevalence with increasing age.

Most true treponemal antibody positives are the "serologic scar" of remote (often treated) infection and pose no risk to blood recipients. A recommendation to discontinue donor screening for syphilis was made in 1985 but not acted upon initially because of the perception that testing might be functioning as a surrogate for HIV or other transfusion-transmissible viruses.[93] This hypothesis has been rejected, but, because the role of syphilis testing in the elimination of transfusion syphilis is unclear, syphilis testing continues even though it has no apparent value. Although small PCR studies of reactive donors have been universally negative, rabbit inoculation studies using samples from confirmed reactive donors will likely be required to eliminate syphilis testing, and it seems unlikely the resources will be found to do a study of the required size.

Lyme Disease

Borrelia burgdorferi is the spirochete that causes Lyme disease, the most common tick-borne infection in North America and Europe. The agent was discovered in 1977 during investigations of an arthritis cluster in Connecticut children. Cases reported to the US CDC doubled between 1992 and 2006 to almost 20,000, continued to rise and have, since 2009, stabilized with annual reporting of confirmed cases between 22,000 and 29,000 (https://www.cdc.gov/lyme/datasurveillance/index.html, Lyme Disease Data and Surveillance). Geographic distribution of cases is highly focused, with the majority of reported cases occurring in 13 northeast, Mid-Atlantic, and north central states. *Ixodes scapularis*, the black-legged tick, transmits *B. burgdorferi* in those areas, and *Ixodes pacificus*, the western black-legged tick, transmits the infection along the Pacific coast. The ticks feed predominantly in late spring and early summer during the nymph stage. Emergence has been associated with environmental changes that increase deer and rodent reservoir populations and changing residential patterns putting humans in more intimate contact with the tick vectors. Rodents are the reservoir. Although deer are not infected, they transport and maintain the ticks. Birds may also play a role in transporting the vector ticks.

The characteristic erythema chronicum migrans ("bull's-eye") rash is present in 70% to 80% of cases within 30 days of infection. The wide variety of clinical findings includes malaise, fatigue, headache, myalgias, large joint arthralgias and arthritis, and neurologic and cardiac signs and symptoms. These may not immediately suggest Lyme disease in the absence of a typical rash or known tick exposure. Serologic testing supports the clinical diagnosis. Unfortunately, poor specificity is recognized with many screening methods, and a two-step approach using a sensitive EIA or immunofluorescence assay (IFA) followed by a confirmatory, more specific, immunoblot is recommended by the CDC.

B. burgdorferi spirochetemia occurs in 44% of patients with clinical Lyme disease and peaks 7 to 10 days after tick bite. The spirochete can survive in red cells, platelets, and frozen plasma for at least the duration of their routine storage. Transfusion transmission of *B. burgdorferi* has been demonstrated in a murine model. Despite these observations, no human transfusion-associated cases have been reported. This may reflect the relatively short spirochetemic phase and low levels of organisms, as well as deferral of donors with nonspecific illness or signs and symptoms of Lyme borreliosis. Although there are no official standards or guidance, it would be prudent for individuals with a history of Lyme disease to be deferred until well and treatment has been completed.

Other Tick-Borne Bacteria

Borrelia miyamotoi, the agent responsible for tick-borne relapsing fever, is transmitted by the same vector as Lyme disease, described above. First isolated and described in 1994, the spirochete has been responsible for influenza-like disease with relapsing episodes of spirochetemia and fever in Asia, Europe, and North America. To date, no transfusion-transmission of *B. miyamotoi* have been shown in humans. Two published studies have suggested a possible risk of human blood transfusion transmission by showing *B. miyamotoi* survival in human RBCs and platelets, as well as transmission in a mouse model.[94,95]

The rickettsia that cause human monocytic ehrlichiosis (HME) and human granulocytic anaplasmosis (HGA; formerly human granulocytic ehrlichiosis) are intracellular bacteria that survive in stored blood. *Ehrlichia chaffeensis* causes HME and is transmitted to humans by Lone Star tick (*Amblyomma americanum*) bites. Most cases occur in the south central and southeastern United States. *Anaplasma phagocytophilum* causes HGA and occurs predominantly in the northeastern and upper midwestern areas of the United States. *I. scapularis* and *I. pacificus* (the Lyme borreliosis vector) transmit the organism. Signs and symptoms include fever, chills, and headache, often associated with thrombocytopenia, leukopenia, and increased liver enzyme levels. Intracellular aggregates of microcolonies of bacteria referred to as morulae appear in monocytes in the HME, and inclusions appear in granulocytes in HGA. Seroprevalence studies in blood donors in endemic areas report 0.5% to 11.3% seropositivity for *A. phagocytophilum* antibodies. At least nine cases of transfusion-transmitted HGA from asymptomatic donors have been recognized after nonleukoreduced RBC transfusion; however, cases have occurred as well following leukoreduction including one from apheresis platelets.[96] Both *Ehrlichia* and *Anaplasma* spp. are white blood cell–associated, and it has been suggested that leukoreduction may mitigate their impact. The infectivity of *Orientia tsutsugamushi*, the rickettsial agent of scrub typhus, is reduced by up to 10^5 by filtration leukoreduction, but infectious *E. chaffeensis* survived in refrigerated red cells and could be isolated from the packed RBCs after filtration.

In a study of heavily tick-exposed military recruits in Arkansas, which included a look back to 10 recipients of transfused units from soldiers infected with *E. chaffeensis* and *Rickettsia rickettsii* (the agent of Rocky Mountain spotted fever [RMSF]), clinical illness did not occur in recipients. One possible RMSF seroconversion was reported. There is a single case report of transfusion-associated RMSF that involved a donor developing symptoms 3 days post-donation. The recipient developed symptoms 6 days post-transfusion.

PARASITIC INFECTIONS

Malaria

Five *Plasmodium* species (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium knowlesi*) and occasionally others cause the protozoan disease malaria. In 2008 243 million cases occurred worldwide, with most in sub-Saharan Africa. Other endemic areas include parts of Asia and South America and more limited areas in Mexico, Central America, and the Caribbean. Of 1478 imported cases in the United States in 2009, 735 were acquired in Africa, 142 in Asia/Western Pacific, and 103 in the Americas.[97] West Africa accounted for most cases associated with Africa, and Honduras, Haiti, and Guyana for most of the cases from the Americas. During 2009 only two cases were acquired in Mexico, both *P. vivax*. In 2003 eight autochthonous infections occurred in Palm Beach, Florida, but none subsequently. Vectorial transmission, overwhelmingly the most common route, is by the bite of an infected female *Anopheles* mosquito. *Anopheles* mosquitoes generally feed between dusk and dawn, thereby limiting the risk to tourists who usually visit malaria areas during daylight hours. Almost three-quarters of those who acquired malaria were visiting friends or relatives in endemic areas. Missionaries and business travelers represent fewer than 20% of infected US citizens. Leisure travelers make up the small remainder.

P. falciparum accounts for 40% to 46% of US cases detected recently, *P. vivax* 11% to 20%, and *P. malariae* and *P. ovale* approximately 2% each. For the remainder, most are undetermined with a few mixed-species infections. *P. knowlesi* has not yet been reported.

Seventy percent of imported cases in the United States occur among returning travelers who were visiting friends or relatives, ethnically and racially distinct from the majority population of the United States (where malaria is not endemic), who return to their homelands (countries where malaria is endemic) to visit friends or relatives. The region of origin is very relevant to measures designed to prevent malaria transmission by transfusion because many of these individuals are semi-immune and therefore can be parasitemic while asymptomatic. In contrast, donors without malarial immunity who travel to endemic areas and become infected are nearly always symptomatic when they are parasitemic and would not be accepted as blood donors. Malaria symptoms occurred within 1 month of arrival in the United States in 84% of those infected with *P. falciparum* and 56% of those with *P. vivax* in 2009. The latter represents almost all cases of relapsing malaria. No acute onsets involving the four most frequent *Plasmodium* species occurred at an interval greater than 1 year.

Slightly over one hundred transfusion cases have been recognized and reported in the United States since 1963. Since 2000 there have been only 11 cases reported. In the majority of cases, transmission would have been prevented had the present donor deferral criteria been appropriately applied.

The incubation period for transfusion-associated malaria ranges from 8 to 90 days. *P. falciparum* has the shortest incubation time, mean 17 days (range, 8 to 36 days) and *P. malariae* the longest, mean 50 days (range, 8 to 90 days). Most cases involved RBC or whole-blood transfusion, although a few transmissions from platelet transfusions have occurred, presumably related to RBC contamination. Transmission from frozen plasma has not been reported.

Current strategies for reducing the low risk for transfusion transmission in the United States involve screening donors through the donor history questionnaire and deferral of residents of non-endemic areas who have traveled to malaria-endemic regions, as defined by the *CDC Health Information for International Travel* document, during the previous 3 months (with exemption for those donating products which will be pathogen-reduced), those with residence in endemic areas for 3 years since their last potential exposure in such regions, and those with a history of malaria for 3 years after resolution.[98] Apart from incomplete elicitation of malaria risk history, residual risk remains because transfusion transmissions of *P. falciparum*, *P. vivax*, and *P. ovale* have been reported 13, 27, and 7 years, respectively, after departure from malarious areas. Because *P. malariae* infection can persist for more than 70 years without symptoms, elimination of transfusion-induced malaria is a practical impossibility. At this time, licensed in vitro screening for at-risk donors using antibody tests, antigen detection, or NAT are unavailable in the United States. It is not clear that the limited commercial potential of assays to be used on a relatively small fraction of donors will justify the investment required to pass the stringent regulatory requirements of a blood donor screening assay. Donor deferral guidelines have been modified in 2014 to reduce the loss of more than 60,000 potential donors with travel to areas of Mexico where the malaria risk is minimal.[99]

Babesiosis

Babesia species that infect humans include *Babesia microti, Babesia duncani* (previously WA1 type), *Babesia divergens* (limited primarily to Europe), *B. divergens*–like (MO1 and EU1), and *Babesia venatorum. B. microti*, an intraerythrocytic protozoan, causes most human infections. The white-footed mouse, *Peromyscus leucopus*, serves as the reservoir and the deer or black-legged tick, *I. scapularis* (also the vector of Lyme borreliosis and HGA), as the vector. Transmission follows bites from infected ticks, primarily nymphs, from May through early September. The defined transmission period has less relevance for transfusion transmission because asymptomatic blood donors can be infected chronically.[100] Most cases occur in seven endemic states, including Massachusetts and its coastal islands, Rhode Island, Connecticut, New York, New Jersey, Wisconsin, and Minnesota. This geographic range has expanded recently, attributed to expansion of white-tailed deer, *Odocoileus virginianus*, populations. Although not a competent host, deer provide a blood meal and transportation for adult ticks to new areas.

The vast majority of both vectorial and transfusion-associated *Babesia* cases involve *B. microti. B. duncani* infections include those previously designated WA1. *B. divergens* cases occur predominantly in Europe. The incubation period varies from 1 to 9 weeks. The severity of illness associated with *Babesia* infections relates more to the infected individual's immune status than the *Babesia* species. The very young, older adults, persons who have had a splenectomy, and those with hereditary hemolytic disorders are at greatest risk for morbidity and mortality. Approximately one-third of infected subjects remain asymptomatic, and parasitemia may persist for more than 2 years. Typical symptoms resemble malaria and include fever, headache, chills, sweats, and arthralgia, myalgia, malaise, nausea, diarrhea, and hemolytic anemia. Parasitemia levels vary from 1% to 2% in otherwise healthy hosts to 85% in immunocompromised and asplenic patients. Case fatality rates approximate 5%.

Case reports of transfusion-associated *Babesia* infections include red cell units stored for up to 42 days. *Babesia* transmission has been reported following transfusion of cryopreserved red cells, and four cases involve whole blood–derived platelet transfusions presumably contaminated with red cells. At least 159 transfusion-associated *B. microti* cases have occurred, primarily in endemic regions, but cases in non-endemic states reflect the interstate movement of both blood components and blood donors and highlight the high index of suspicion required to recognize cases.[101] More than three-quarters of the reports occurred during the past decade. The all-cause mortality rate approaches 19%. Babesia represented the highest number of reported transfusion-related fatalities to the FDA from any single microbial infection in the periods of 2008 to 2012 and again in 2010 to 2014 including 8 of 21 (38%) and 4 of 15 (27%), respectively. The total number of transfusion-related fatalities in these periods was 198 and 176, respectively (www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/ReportaProblem/TransfusionDonationFatalities/). There are three reports of transfusion-transmission involving *B. duncani*, and single cases have been reported from Japan (*B. microti*–like) and Germany.

Babesiosis has been made a nationally notifiable infection as of 2011 and is included in the nascent biovigilance network of the National Healthcare Safety Network, so more accurate measurements of transfusion risk may become available in the future. In 2011 to 2013 up to 29 states reported a total of 3857 cases nationally of which 95% occurred in seven states in New England and the upper Midwest and increased to 98.5% in nine states (adding New Hampshire and Maine) (http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6127a2.htm). Transfusion-transmission risk estimates in endemic states have occurred with the advent of investigational testing and are about 1 per 18,000 red cell units transfused in the highly endemic states of New England to an overall risk of approximately 1 per 100,000 units throughout the all nine endemic states mentioned (including New Hampshire and Maine, where an increasing number of transfusion-related cases have been reported).

Febrile patients must be queried for a transfusion history and babesiosis considered when transfusion has occurred. Diagnostic laboratory evaluation includes blood smear examination, which requires differentiation of *Babesia* spp. from *Plasmodium* infections. Tetrad or "Maltese cross" forms are diagnostic for *Babesia* but occur infrequently. Diagnostic testing most frequently involves indirect IFA testing for identifying persons with low-level parasitemia such as patients with chronic infections but remains positive for up to 5 years after resolution or cure of babesiosis. PCR testing is more sensitive for detecting acute infections before seroconversion.

While blood donation screening has proven to be highly effective[102]; testing was sought in the absence of universal pathogen reduction. IND testing was conducted using a NAT by PCR in conjunction with antibody assay as well as a more sensitive NAT-only assay. No transmission of *Babesia* was seen in any tested units. As a result, the NAT-only assay was approved for FDA licensure in 2019 and new guidance was released by FDA for screening donations in endemic areas (14 states, plus the District of Columbia).[103] Along with the new screening guidelines, FDA included new deferral guidance, which lessened the deferral period for reactive donors from indefinite to a 2-year deferral.

Leishmaniasis

Phlebotomine (Old World) and *Lutzomyia* (New World) sandfly bites transmit *Leishmania* infections to humans in most of the tropical and subtropical world. *Trypanosomatidae* of various species cause visceral infection also known as kala-azar (*L. donovani*, *L. infantum*, and others). Additional species are involved in cutaneous and mucocutaneous infections (*L. tropica*, *L. major*, *L. mexicana*, *L. braziliensis*, and others given a variety of local names). In addition, transplacental, sexual, and transfusion transmissions occur.[104] The promastigote form of the parasite resides in the gastrointestinal tract of sand flies and is inoculated into humans through a skin bite. In humans, promastigotes are phagocytosed by monocytes, where they transform into amastigotes that reproduce and reside in macrophages and the reticuloendothelial system. Organisms in monocytes and free amastigotes are released during refrigerated storage, transform back into extracellular promastigotes, and mediate transfusion transmission. *L. tropica* also survives in monocytes contained in frozen red cell preparations and in platelet concentrates stored at room temperature. At least 10 cases of transfusion-associated leishmaniasis attributed to *L. donovani* have been reported in endemic areas, mostly in young children or neonates. A probable case of platelet transfusion–transmitted *L. donovani* was reported in India. A presumed case of transfusion-transmitted *L. mexicana* in a renal transplant recipient was mistakenly diagnosed as Chagas disease because of serologic cross-reactivity between *Trypanosoma cruzi* and *Leishmania. L. infantum* DNA was amplified from 6% of peripheral blood mononuclear cells of blood donors with *Leishmania* antibodies in the Balearic Islands. Several animal model studies also demonstrate transmission by blood transfusion.

Asymptomatic infections occur frequently in healthy donors exposed in endemic areas, and the organisms may circulate in peripheral blood more than 1 year following exposure. Foxhounds infected with *Leishmania* species have been found in 18 US states and two Canadian provinces, but transmission has not extended to humans.

Following reports of *L. tropica*–related viscerotropic leishmaniasis in veterans of Operation Desert Storm, between August 1990 and December 1992, those serving in that theater of operations were deferred from blood donation for 1 year. The deferral period reflected the development of fever, malaise, abdominal pain, and intermittent diarrhea up to 7 months after return to the United States. *L. tropica* was found in the bone marrow of seven patients and in the lymph nodes in one. When intracellular amastigotes were seen in the peripheral blood of the one patient in whom this was studied following reports of cutaneous and visceral leishmaniasis among troops involved in the Afghanistan and Iraq wars, a similar 1-year deferral following departure from Iraq and Afghanistan was implemented. The military continues to enforce lifetime deferral for any clinical history of *Leishmania* infection.

The possibility of transmission to humans during military deployment and travel and the large number of military personnel returning from Iraq and Afghanistan raise concerns about future transfusion transmission. To date, there are no cases of transfusion-transmitted leishmaniasis in the United States. The widespread use of leukoreduction filters likely has a beneficial role because these filters reduce both intracellular and extracellular parasite concentrations by 3 to 4 logs.

Toxoplasmosis

Toxoplasmosis is caused by the obligate intracellular protozoan parasite *Toxoplasma gondii*, whose usual host is the domestic cat. The parasite is transmitted by exposure to cat feces, by eating raw or undercooked pork, goat, lamb, beef, or wild game, and congenitally. In the NHANES from 1999 to 2004, 24.8% of foreign-born US residents age 12 to 49 years of age, compared with 8.2% of US–born residents, had serologic evidence of infection; approximately 50% of those with antibody harbor parasites in tissue. Transfusion-associated disease has been described in immunocompromised patients receiving granulocyte concentrates from donors with chronic myeloid leukemia who would not qualify as blood donors currently. One possible transfusion-related case involves a platelet transfusion. Red cells and frozen plasma transmission have not been reported.

Chagas Disease

The protozoan parasite *T. cruzi* causes Chagas disease. The infection is widespread in Latin America; approximately 8 to 10 million people are affected. Humans become infected when bitten by *T. cruzi*–infected insects of the *Reduviidae* family (triatomine, assassin, kissing, or chinch bugs). Congenital transmission from mother to fetus, organ transplantation, blood transfusion, and ingestion are recognized routes as well. Once infection occurs, low-level, intermittently detectable parasitemia usually persists for life. Treatment with benznidazole or nifurtimox can reduce the risk for chronic sequelae, but neither of these drugs is FDA approved and access to only one of these is through an IND with the CDC. Treatment is most effective during the acute stage of infection. At least 18 mammalian species in the United States serve as reservoirs, including armadillos, opossums, and raccoons, and vectors are present in the lower two-thirds of the country; autochthonous vector transmission is rare but has been increasingly reported especially in rural areas of Texas. CDC estimates at least 20 states have had isolation of the insect vector and 17 states with the mammalian reservoir. An estimated 300,000 people in the United States and Canada are infected with *T. cruzi;* most are immigrants from Latin America. *T. cruzi* organisms remain viable in whole blood stored at refrigerator temperatures for 18 days, for longer than 8 months in citrated blood samples stored at room temperature, and following freezing and thawing. In South America, early data suggested that approximately 13% to 49% of recipients of fresh whole blood from parasitemic donors become infected. There has been concern that additional transfusion-associated Chagas disease cases will occur as immigration increases to the United States from Central and South America.

American trypanosomiasis, or Chagas disease, consists of an acute phase that varies from asymptomatic to manifestations that include fever, skin rash, and conjunctivitis with edema around the eyelids, lymphadenopathy, and hepatosplenomegaly. The acute phase usually resolves in 4 to 8 weeks unless severe myocarditis or meningoencephalitis intervenes. The latter is associated with fatal outcomes. Intracellular *T. cruzi* amastigotes remain in cardiac and skeletal muscle following the acute phase. Following an indeterminate stage of undetermined duration, chronic disease occurs in 20% to 30% of infected patients, manifesting as cardiac disease (initially conduction and left ventricular wall abnormalities), megacolon, or achalasia. Diagnosis is made on clinical and serologic grounds most often. Xenodiagnosis, hemoculture, and nucleic acid amplification tests are also available.

Donor risk factors for transfusion-transmitted *T. cruzi* infection include birth or residence in endemic regions such as Central America, South America, or Southeastern Mexico; living in dwellings with palm leaf–thatched roofs or mud walls, where vector insects reside; oral intake of contaminated foodstuffs; and receipt of unscreened blood transfusions in Latin America. Among donors who lived in poor housing or received a blood transfusion in endemic areas, 3% to 4% had *T. cruzi* antibodies. One study, conducted in California in the 1990s, found that 1 per 340 blood donors had a risk factor for Chagas disease. A large survey conducted from 1994 to 1998 in Los Angeles and Miami among immigrant blood donors from endemic areas found *T. cruzi* seroprevalence rates of 1 per 7500 and 1 per 9000, respectively. However, none of the 18 recipients in this survey who received blood from a seropositive donor, and who were available for testing, had evidence of infection.

A look-back study involving blood donations in Mexico made before determining the donors were *T. cruzi*–seropositive, found four of nine recipients of subsequently determined seropositive whole blood or platelets to be seropositive.

Since 1987, 30 years before testing started in the United States and Canada, seven cases of transfusion-associated Chagas disease were reported in those countries; symptoms developed 2 to 3 months after transfusion. In six cases, platelets were the implicated component; and the unit in the seventh case was not identified. In each of the six cases, the implicated donor emigrated from a *T. cruzi*–endemic region (Bolivia, Mexico, Paraguay, and Chile) between 16 and 33 years before the implicated donation. *T. cruzi* may separate with platelets, or room-temperature storage may favor parasite survival. In addition, acute Chagas disease has been reported in organ transplant recipients. More recently, two transfusion-related infections were identified in the United States as a result of recipient tracing (look-back) studies (but these represented fewer than 1% of all studied individuals exposed to transfusion of blood from infected donors; see later). Additional transfusion-associated cases have been reported from Spain, all derived from donors who had emigrated from South America for a total of 20 cases ever documented when combining all reported transfusion-associated cases from the United States, Canada, and Spain, the countries with the highest immigration rates from Latin America.[105]

The assumed increasing prevalence of *T. cruzi*–infected blood donors with immigration into the United States from Latin America, the reports of transfusion-associated cases, and some autochthonous infections triggered efforts to mitigate the risk for transfusion-transmitted Chagas disease in the United States. Questioning donors about region of birth or extended stay and transfusion in Chagas-endemic areas could interdict 75% of infected donors but would result in deferral of large numbers of non-infected donors. Leukoreduction decreases *T. cruzi* transmission in a mouse model by 50% to 70%, consistent with *Leishmania* and the rickettsia *Anaplasma*. Pathogen-reduction techniques successfully decrease *T. cruzi* viability in plasma and cellular products.

Serologic screening, used for many years in Latin America, was chosen as the preferred strategy for the United States. The first serologic test for screening blood donors, based on a *T. cruzi* whole-parasite lysate, achieved FDA licensure in December 2006, and voluntary screening commenced in early 2007. Approximately 1 per 30,000 donations showed confirmed reactive serologic results, a lower prevalence than estimated. In 2010 the FDA licensed a second assay that uses chimeric recombinant antigens and in 2011, a licensed supplemental test using the same antigen constructs was FDA licensed. Seropositive donors are overwhelmingly immigrants from *T. cruzi*–endemic countries with asymptomatic chronic infections, although a small number of seropositive donors may have acquired the infection in the United States via vertical transmission from infected immigrant mothers, or very rarely by autochthonous vectorial transmission. From the investigation of antibody-positive donors lacking any immigration or maternal risk factors, autochthonous transmission has been estimated to occur at the rate of 1 per 354,000 donors.[106]

Look-back studies involving recipients of prior donations from those found positive for *T. cruzi* antibodies on a subsequent donation showed rates of transfusion transmission much lower than predicted. Only two occurred (0.8%), both from the same apheresis platelet donor born in Argentina, among 253 recipients tested. In light of these findings, testing donors is now required only once rather that at each donation.[36,107] Concern that those tested once might contract *T. cruzi* during travel or within the United States seems unfounded in that no seroconversions have been observed in more than 4 million blood donors during 6 million person-years of follow up.[36] The unexpectedly low rate of transmission may relate to differences in blood component processing and storage in the United States compared with Latin America (absence of the transfusion of fresh whole blood), some underrepresentation of platelet donors in the look backs completed to date, or other biases. Although all donors are asked a question about having a history of Chagas disease, with the advent of sensitive testing, the question has no residual value and has been removed from the donor history questionnaire.[107,108]

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

The transmissible TSEs (prion diseases) are rare, lethal neurodegenerative diseases generally accepted to be caused by nucleic acid–free proteins called $\mathrm{PrP^{TSE}}$, as distinguished from the normal cellular protein, $\mathrm{PrP^{C}}$. The existence of additional factors has not been excluded, but current consensus supports the involvement of infectious proteins. $\mathrm{PrP^{TSE}}$ is an abnormal conformation of $\mathrm{PrP^{C}}$ that induces transformation (recruitment) of additional $\mathrm{PrP^{C}}$ to $\mathrm{PrP^{TSE}}$, resulting in deposits of insoluble aggregates in central nervous system tissue followed by progressive dementia and other characteristic neurologic findings. Non-variant Creutzfeldt-Jakob disease (CJD) is diagnosed at a rate of approximately one case per million population per year worldwide. It occurs as sporadic CJD (85% of cases), vertically transmitted familial diseases caused by germline mutations in the human *PRNP* gene (e.g., fatal familial insomnia and Gerstmann-Straüssler-Scheinker syndrome), and less commonly through iatrogenic transmission of infection (e.g., from dura mater implantation, contaminated surgical equipment, injection of human pituitary-derived growth hormone, or corneal transplant) and historically has been known to be spread horizontally (i.e., Kuru associated with consumption of human brain during ritual cannibalism).

There are no documented cases of transfusion transmission of sporadic CJD, the familial or iatrogenic forms, and cohort studies of intensively transfused patient groups have failed to establish any epidemiologic association in both the United Kingdom and the United States.[35,109] In an ongoing look-back effort, no cases of CJD have been observed among 826 recipients (of whom 154 were still alive as of December 31, 2014) of blood components from 65 donors subsequently diagnosed with CJD.[109] A case-control study of CJD patients, compared with control patients without CJD, found a fivefold increased risk for CJD with a history of transfusion more than 10 years before TSE onset, but the authors recognized critical sources of bias in their methods and their findings are unconfirmed. Nevertheless, as a result of the iatrogenic transmissions and long incubation period of the disease (as demonstrated in growth hormone transmissions), concern arose in the mid-1990s that CJD transmission could occur from asymptomatic donors to transfusion or derivative recipients. This theoretical risk resulted in lifetime donor deferral requirements for iatrogenic exposure to or a family history of classic CJD.

Like non-variant CJD, vCJD is a fatal, degenerative neurologic disease. It occurs in younger patients than classic CJD and has distinctive clinical, radiographic, histopathologic, and biochemical features. The first reports of vCJD from the United Kingdom were published in 1996. The etiologic agent is the same prion that causes BSE or "mad cow disease." Transmission of the BSE prion to humans occurred by consumption of beef and other bovine products containing infectious neural or reticuloendothelial tissue. In the United Kingdom the vCJD epidemic followed a massive epidemic of BSE in the 1980s and 1990s. The latter was traced to the recycling of material from dead sheep and cattle (offal) into feed for cattle. This practice was banned in 1988, and the vCJD outbreak subsided after a peak of 28 cases in 2000. The number of new vCJD diagnoses in the United Kingdom rose steadily in the first few years after 1995 from 3 in 1995 to 28 in 2000, but decreased since then to 5, 5, 5, 1, 3, 3, and 2 from 2005 to July 2011 and 2 additional since then totaling 177 definite or probable cases of vCJD reported in the United Kingdom.[110] An additional 52 cases have been diagnosed elsewhere, mostly in France and several other European countries. A few cases have been identified outside Europe, including four cases in the United States (two associated with exposure in the United Kingdom, one in Saudi Arabia, and one with international travel not linked to a country where other vCJD cases were seen), two from Canada, and one each from Japan, Taiwan, and Saudi Arabia. Most, but not all of the patients with non-European cases had more than 6 months' exposure in the United Kingdom during the BSE epidemic. Although it appears that the vCJD outbreak is waning (and is much smaller than initially feared), concern persists that there could be a second wave of the epidemic caused by delayed onset of the disease in infected individuals. This is based in part on observations of abnormal prion protein accumulation in random surgical tissue samples in the United Kingdom, which may represent preclinical vCJD disease. In one retrospective study, 3 of 12,674 appendectomy and tonsillectomy specimens from persons 20 to 29 years of age were positive. Furthermore, a critical polymorphism at codon 129 of the PrP^C gene coding for methionine or valine leads to variation in the susceptibility to and incubation period of human TSEs. All of the clinical cases reported to date are methionine homozygotes. Because only 37% of the general British population is homozygous for methionine, and are maximally susceptible to vCJD, a larger population (52%) of heterozygotes and valine homozygotes (11%) may be at risk for asymptomatic infection in a prolonged incubation period.

Four transfusion-transmitted infections with the vCJD prion have been reported in the United Kingdom. Although they may have developed vCJD independent of transfusion, this possibility is regarded highly unlikely based on epidemiologic and statistic considerations. Three of the four cases were diagnosed with clinical vCJD 6.5, 7.8, and 9 years after receiving nonleukocyte reduced RBCs or a blood component from two different donors who developed clinical symptoms of vCJD 40 and 21 months after donating. These three with symptomatic disease were homozygous for methionine at codon 129. The fourth case was heterozygous (methionine/valine) and had no clinical signs or symptoms of vCJD at death from unrelated causes but had abnormal prion protein aggregates in lymphoid (but not neural) tissues at autopsy and was considered to have preclinical infection. Five years before death the recipient received non-leukocyte reduced RBCs from a donor who developed clinical vCJD 18 months after donating. These four cases represent 6% of the 67 UK recipients who received blood components from 18 different donors subsequently diagnosed with vCJD (and an estimated 23% of exposed methionine homozygotes). In light of these cases and animal transfusion experiments, TSE transmission and disease from transfusion is no longer regarded as a theoretical event.[35] A single case reports a potential epidemiologic link between exposure to plasma derivatives and transmission of the agent to a recipient.

Prion-removal strategies (e.g., affinity filters) remain under evaluation, especially in the United Kingdom, but none is expected to be suitable for consideration for use in the United States in the immediate future. There are currently no blood donor screening tests for vCJD, leaving risk mitigation dependent on deferral of donors that could have asymptomatic infection. Initially, primarily on the basis of the prominent distribution of vCJD prion in reticuloendothelial tissue compared with classic prion protein (PrP^C), on subsequent reports of animal and human infection by transfusion, and then on the early observation that nearly all cases of vCJD were associated with potential exposure in the United Kingdom or to UK bovine products, the FDA adopted and has modified donor-deferral policies sequentially since 1999.[111] The first called for indefinite deferral of donors who had spent more than 6 months in the United Kingdom from 1980 to 1996, before control of the food chain and of recipients of bovine insulin from the UK. Models predicted that this would remove approximately 90% of the risk at a "cost" of deferring approximately 5% of otherwise eligible donors. These were subsequently expanded to include US military personnel and their dependents who spent certain durations on bases in the European Union where UK beef was imported during the BSE epidemic and recipients of transfusions in the United Kingdom and France during the peak risk periods of their BSE epidemics. Experience at US blood centers has largely confirmed the donor loss predictions of the FDA models. In the midst of the SARS-CoV-2 pandemic, the US FDA updated their donor deferral criteria using recent epidemiologic data published on risk of vCJD and CJD. This guidance allows for the removal of the following deferrals: Human Growth Hormone medication, blood relatives with CJD, time spent in countries other than the UK, France, and Ireland from 1980-present, time spent on military bases in Europe, and a history of injection of bovine insulin.[111]

Chronic wasting disease (CWD) of deer and elk is prevalent at rates as high as 15% in cervid populations in at least 24 states within the United States and Canada. Concern has been expressed that, given the popularity of hunting, there may be risk for exposure to and infection with the CWD prion during handling or consumption of infected animals. Apparent clusters of classic CJD in hunters have been alleged, but on full evaluation have not been shown to have a relationship to the CWD agent. There is currently no plan to intervene for this theoretical risk in hunters who donate blood beyond hygienic measures when handling cervids or their tissues.

FUTURE DIRECTIONS

The residual risk for transmitting HIV, HBV, and HCV is less than 1 per million units transfused, an extremely low rate. In contrast, platelet septic events are reported at a frequency of 1 per 100,000 units.

Transmission of known, emerging infectious agents such as dengue, Zika virus, *B. microti*, and those currently unrecognized remain problematic. Continued safety of the blood supply requires constant vigilance, early detection, reporting of untoward events, and excellent communication and cooperation between those providing blood components and those prescribing them.

CHAPTER 119

PEDIATRIC TRANSFUSION MEDICINE

Bentley B. Rodrigue and Steven R. Sloan

A variety of neonatal and pediatric patients require blood component transfusions. This chapter focuses on aspects of blood-bank laboratory testing, blood products and components, transfusion indications, and potential adverse events that are specifically relevant to neonates and children.

PEDIATRIC BLOOD BANKING

Blood and Blood Components

Several different blood components, including whole blood, reconstituted whole blood, red blood cells (RBCs), platelets, plasma, and cryoprecipitated antihemophilic factor (CRYO) may be available from a blood bank for transfusion. Recently, additional components have become available in the United States. They are photochemically treated INTERCEPT platelets and plasma, and solvent detergent–treated plasma, Octaplas. The availability of specific component types varies between blood suppliers.

- Whole blood is infrequently used and may not be available from a particular blood bank or blood supplier, but it may be available on request and is used by some pediatric cardiac surgery services. Whole blood contains all RBCs, plasma, platelets, and an anticoagulant-preservative solution containing citrate, phosphate, dextrose, and possibly adenine.
- RBC units mostly contain RBCs but also contain some plasma and a preservative solution. Most RBC units contain an additive preservative solution that includes some combination of adenine, dextrose, and mannitol. Additive solutions are safe for relatively small ($\leq$20 mL/kg) transfusions. There are concerns over the safety of these additives given in large transfusions to neonates, and their safety in this setting has never been proven in a randomized clinical trial. In view of this concern, some hospital blood banks provide nonadditive RBC units or wash additive units intended for large transfusions to neonates. Because many blood centers provide only additive RBC units to hospital blood banks and washing an RBC unit takes approximately 1 hour, blood banks have been unable to supply RBC units without additives in many situations. Thus, many institutions now have significant experience transfusing large volumes of additive RBC units to neonates and have not noticed any problems.
- Two general types of platelet units are available in the United States, although any one blood bank or hospital may stock only one of these types. These two types, whole blood–derived platelets (platelets) and platelets collected by apheresis (pheresis platelets), differ in their size. A platelet unit contains approximately 5.5 to 10×10^{10} platelets in about 50 mL, whereas a pheresis platelet unit contains at least 3×10^{11} platelets in about 200 mL. It is often easier to use platelet units for small children because pheresis platelets usually need to be aliquoted to provide the correct dose. However, many blood centers exclusively provide only one type of platelet component. Recently, two modifications of platelet components were approved in the United States, although these had been in use in other countries for several years.
    - Platelets that have undergone pathogen inactivation using the INTERCEPT Blood System (Cerus Corporation, Concord, CA) that mixes amotosalen HCl, a synthetic psoralen compound that intercalates with nucleic acid and, on activation with ultraviolet (UV) light, cross-links pathogen and white blood cell DNA, inhibiting replication.[1] Almost all of the amotosalen, a potential carcinogen, is removed during processing. However, INTERCEPT platelets are contraindicated for neonatal patients treated with phototherapy devices emitting wavelengths <425 nm due to potential erythema from interaction between UV light and amotosalen. Fortunately, phototherapy devices currently used in the United States emit higher wavelength light in the 430 to 490 nm range.
    - Platelets stored in a platelet additive solution (PAS). PAS platelets contain very little plasma, reducing the risk of allergic reactions and transfusion-related acute lung injury (TRALI) but also lowering the dose of coagulation factors contained in the platelet component.
- Plasma is frozen to retain functional plasma proteins including clotting factors. Depending on the timing of freezing and thawing, the component may be called fresh frozen plasma (FFP) or another name. However, all of these plasma components contain all the necessary clotting factors. Two pathogen-inactivated plasma products that had been available in several countries are now available in the United States:
    - INTERCEPT (Cerus Corporation, Concord, CA) treated plasma using the same system as described above.
    - Octaplas (Octapharma, Hoboken, NJ) is a filtered pooled plasma product that is subjected to solvent/detergent treatment to inactivate lipid-enveloped viruses.[2] Its safety and efficacy in pediatric patients have not been evaluated, which would be important in neonates whose coagulation system regulation differs from adults. Specifically, Octaplas contains low concentrations of protein S and α2-antiplasmin, two inhibitors of the coagulation system that are present in low concentrations in neonates.[3,4]
- Cryoprecipitate is prepared from plasma and contains high concentrations of fibrinogen.
- Because pediatric patients require smaller doses of blood components, they often require only a portion of a component.
- RBCs are stored refrigerated and hence can be prepared in aliquots as needed if the blood bank has the necessary equipment. Alternatively, the blood center can collect RBC units into a collection system in which additional bags are attached for dispensing aliquots. Whole blood is also stored refrigerated, but its use is limited and it is almost never prepared in aliquots.
- All platelet components are stored at room temperature under constant agitation and can be prepared in aliquots when needed in the blood bank if the blood bank has the necessary equipment and supplies. However, 1 unit of whole blood–derived platelets does not contain many doses, even for infants, and most blood banks do not aliquot them.
- All plasma products are stored frozen and are not generally aliquoted after thawing. However, many blood centers will prepare plasma aliquots before freezing.
- Because even small infants rarely require less than 1 unit of cryoprecipitate, this component is rarely prepared in aliquots.

Directed Donations

Families sometimes prefer to donate blood for their children using a process known as directed donations, and some blood banks permit this. If this is done without medical reason, it offers no benefit and there are potential risks. Although directed donors need to go through the same screening and infectious disease testing process as all allogeneic blood donors, some studies suggest that directed donors have a slightly higher risk for infectious disease transmission.

In addition, directed donors may be a poor choice for immunologic reasons. For example, if a neonate has alloimmune thrombocytopenia or anemia, the pathologic antibody is a passively acquired maternal antibody directed against inherited paternal antigens. In this case, blood donated by the father would be recognized by the antibody in the baby's circulation and cleared just as the neonate's own platelets or erythrocytes are cleared. Another example in which immune concerns make directed donors a poor choice involves transplants. Some patients may require a future tissue or bone marrow transplant, and blood relatives often serve as the best donors for such transplants. However, prior transfusions from relatives may sensitize the patient's immune system to antigens present on the tissues of blood relatives, complicating those potential tissue or bone marrow transplants.

TECHNICAL CONSIDERATIONS/MECHANICAL DEVICES

Smaller pediatric patients require small transfusions administered at slow rates. Aliquots of components often need to be prepared. This can be performed by collecting blood into collection bags interconnected with sterile tubes or by attaching additional containers to a standard blood component by using a sterile docking device that produces a sterile weld between two separate tubing sets.

Blood components must be filtered to remove microaggregates before transfusion. For an adult patient, this is normally accomplished by transfusing the component through a filter contained within the blood administration set. These standard blood administration sets are not ideal for transfusing small patients because 20 to 40 mL of the component is lost in the dead space of the administration set. Pediatric microaggregate filters with much smaller dead space are available.

For nonbleeding patients, blood components should be transfused at a rate of no more than 5 mL/kg/h. For infants, this corresponds to a lower rate than can be regulated by most standard infusion pumps. Hence, these transfusions are usually performed using syringe pumps, with the blood component aliquot transferred to a syringe prior to the transfusion. Often, the blood bank prepares aliquots of a blood component through a pediatric microaggregate filter directly into a syringe, eliminating the need for bedside microaggregate filtration.

TRANSFUSION MEDICINE: GENERAL INDICATIONS AND DOSING

Indications for Red Blood Cells Transfusion in Neonates, Children, and Adolescents

Neonates Less Than 4 Months Old

RBC transfusions are more commonly administered to hospitalized neonates than any other pediatric patient age group, and RBCs are the component most often transfused in this population. Symptomatic anemia is the major indication for simple transfusion, and an RBC transfusion should be considered when the venous hemoglobin is less than 10 to 13 g/dL depending on the patient's clinical condition or when a neonate has lost approximately 10% of his/her blood volume. A transfusion dose of 10 to 15 mL/kg of RBCs should yield an increase in the neonate of 2 to 3 g/dL of hemoglobin after transfusion.

TABLE 119.1 **Guidelines for Transfusion of Red Blood Cells in Infants Less Than 4 Months of Age**

1. Hematocrit <20% with low reticulocyte count and symptomatic anemia (tachycardia, tachypnea, poor feeding)
2. Hematocrit <30% and
    a. On <35% oxygen hood, or
    b. On oxygen by nasal cannula, or
    c. On continuous positive airway pressure and/or intermittent mandatory ventilation on mechanical ventilation with mean airway pressure <6 cm of water, or
    d. With significant tachycardia or tachypnea (heart rate >180 beats/min for 24 h or respiratory rate >80 breaths/min for 24 h)
    e. With significant apnea or bradycardia (more than six episodes in 12 h or two episodes in 24 h requiring bag and mask ventilation while receiving therapeutic doses of methylxanthines), or
    f. With slow weight gain (<10 g/day observed over 4 days while receiving >100 kcal/kg/day)
3. Hematocrit <35% and
    a. On >35% oxygen hood, or
    b. On continuous positive airway pressure/intermittent mandatory ventilation with mean airway pressure >6–8 cm of water
4. Hematocrit <45% and
    a. On extracorporeal membrane oxygenation (ECMO), or
    b. With congenital cyanotic heart disease

RBC, Red blood cell.

Two randomized clinical trials of premature infants in neonatal intensive care units, examining restrictive versus liberal RBC transfusion practices, had conflicting results.[5,6] Therefore, most guidelines have been based on experience rather than evidence-based medicine (Table 119.1). A retrospective review investigating preoperative blood transfusions (PBTs) in surgical neonates revealed that when using a propensity score-matched model, PBTs are independently associated with increased morbidity and mortality, acknowledging that prospective studies are still needed.[7] Notably, previous data surrounding the contribution of RBC transfusion and anemia to necrotizing enterocolitis in very low birth weight (VLBW, ≦1500 g) infants has been inconsistent. However, a secondary, prospective, multicenter observational study has shown that it is severe anemia, and not transfusions themselves, that is the associated risk factor for necrotizing enterocolitis.[8] An ongoing study (http://clinicaltrials.gov/01702805) has the promise of providing definitive evidence to inform RBC transfusion practice in this population.[9]

With respect to blood product age, one prospective randomized clinical trial found equivalent clinical outcomes in neonates transfused with fresh RBCs stored for less than 7 days when compared to those transfused with standard-issue RBCs with a mean age of 14.6 days, although some have criticized the generalizability of the study results.[10,11]

Older Infants, Children, and Adolescents

RBC transfusion indications for infants older than 4 months and for young children are similar to those of adults. However, there are several noteworthy differences between children and adults: total blood volume, ability to tolerate blood loss, and age-specific hemoglobin levels (Table 119.2). In infants, RBC transfusions are primarily given for surgical losses, anemia of chronic diseases, and malignancies. Infants inherently have lower hemoglobin levels than adults and remain asymptomatic at lower hemoglobin concentrations, especially if the anemia occurs gradually. Even with these physiologic differences, general transfusion-trigger guidelines for pediatric intensive care unit patients are similar to those for adults, with a transfusion

TABLE 119.2 **Guidelines for Transfusion of Red Blood Cells in Patients More Than 4 Months of Age**

1. Emergency surgical procedure in patient with significant postoperative anemia
2. Preoperative anemia when other corrective therapy is not available
3. Intraoperative blood loss ≥15% total blood volume
4. Hematocrit <21%–24%
    a. In perioperative period, with signs and symptoms of anemia
    b. While on chemotherapy/radiotherapy
    c. Chronic congenital or acquired symptomatic anemia
5. Hematocrit <21%, hemodynamically stable patients >3 days old in the pediatric intensive care unit
6. Acute blood loss with hypovolemia not responsive to other therapy
7. Hematocrit <40% and
    a. With severe pulmonary disease
    b. On ECMO
8. Sickle cell disease (may require exchange transfusion)
    a. Cerebrovascular accident
    b. Acute chest syndrome
    c. Splenic sequestration
    d. Aplastic crisis
    e. Recurrent priapism
    f. Preoperatively when general anesthesia is planned (target hemoglobin 10 mg/dL)
9. Chronic transfusion programs for disorders of RBC production (e.g., β-thalassemia major and Diamond-Blackfan syndrome unresponsive to therapy)

ECMO, Extracorporeal membrane oxygenation; *RBC*, red blood cell.

TABLE 119.3 **Guidelines for Transfusion of Platelets in Neonates and Older Children**

Platelet Count <150,000/μL

1. Platelet count 5000–10,000/μL with failure of platelet production
2. Platelet count <25,000–30,000/μL in neonate with failure of platelet production
3. Platelet count <25,000–50,000/μL in stable premature infant
    a. With active bleeding, or
    b. Before an invasive procedure with failure of platelet production
4. Platelet count <50,000–100,000/μL in sick premature infant
    a. With active bleeding, or
    b. Before an invasive procedure in patient with DIC

Without Thrombocytopenia

1. Active bleeding with qualitative platelet defect
2. Unexplained excessive bleeding during cardiopulmonary bypass
3. Patient receiving ECMO with
    a. Platelet count <50,000–100,000/μL
    b. Higher platelet counts and bleeding

trigger of 7 g/dL of hemoglobin for hemodynamically stable patients being shown to be safe for these patients.[12] This threshold has also been found to be safe for hematopoietic progenitor cell (HPC) transplant patients.[13] In pediatric intensive care unit patients, consensus has arrived at a strong recommendation to transfuse when hemoglobin drops to below 5 g/dL; however, at higher hemoglobin levels, there is less agreement regarding RBC transfusion practices.[14] The usual dose of RBCs is 10 to 15 mL/kg.

There is no evidence that pediatric patients benefit from transfusion of RBCs of a particular age. A multicenter, blinded, randomized clinical trial showed that among critically ill pediatric patients, fresh RBCs did not reduce the incidence of new or progressive multiple organ dysfunction syndrome (including mortality) when compared to the use of standard-issue RBCs.[15]

Platelets

Platelet transfusion support in pediatric patients is usually intended as a prophylactic strategy to prevent bleeding (Table 119.3). In sharp contrast to adults, who rarely develop spontaneous severe bleeding until their platelet counts fall below 10,000/μL, preterm infants with other complicating illnesses may bleed at higher platelet counts. The increased risk may be secondary to (1) lower levels of plasma coagulation factors, (2) natural anticoagulants that potentiate thrombin inhibition, (3) intrinsic or extrinsic platelet dysfunction, and (4) increased vascular fragility. Platelet counts and function in older children are similar to those of adults, and the indications for platelet transfusions do not differ from the indications for adults. The prophylactic platelet transfusion thresholds in premature infants have historically been quite controversial and based primarily on expert consensus rather than evidence-based medicine. However, a new multicenter randomized trial supports using a platelet-count threshold of 25,000/μL to guide the administration of prophylactic platelet transfusions in premature neonates who are not bleeding. In this study, it was shown that premature infants randomly assigned to receive prophylactic platelet transfusions at a threshold of 50,000/μL had a significantly higher rate of death or major bleeding event.[16]

Frozen Plasma and Cryoprecipitate

Frozen plasma is used in preterm and term infants most commonly to treat multiple factor deficiencies or vitamin K deficiency, a condition that can occur in infants not prophylactically given vitamin K after birth, especially if the mother ingested certain drugs during pregnancy such as warfarin, cephalosporins, or some anticonvulsants (Table 119.4). Dosing for all pediatric patients is 10 to 15 mL/kg. This should result in an increase in all factor activity of 15% to 20% unless there is a marked consumptive coagulopathy. As mentioned previously, solvent detergent-treated plasma, Octaplas, may not be as therapeutic for neonates as it has low concentrations of protein S and α2-antiplasmin.

Cryoprecipitate is used primarily to treat disorders resulting from a decrease in or dysfunction of fibrinogen or factor XIII deficiency. These indications are similar to those for adults. Children should receive 1 to 2 units of CRYO/10 kg patient weight. One unit or less of cryoprecipitate is usually sufficient to achieve hemostatic levels in infants and premature infants. The expected rise in fibrinogen should be 60 to 100 mg/dL.

Granulocytes

Granulocytes, whose efficacy, especially at low doses, is unproven, may be indicated for neutropenic children with infections unresponsive to standard antimicrobial therapy.[17] In addition, children with granulocyte dysfunction (e.g., chronic granulomatous disease [CGD]) severe infections may also benefit from granulocyte transfusions. However, patients with CGD are at significant risk for

TABLE 119.4 **Guidelines for Transfusion of Frozen Plasma and Cryoprecipitate in Neonates and Older Children**

Frozen Plasma

1. Support during treatment of DIC
2. Replacement therapy
   a. When specific factor concentrates are not available, including but not limited to, antithrombin, protein C or S deficiency, and factor II, factor V, factor X, and factor XI deficiencies
   b. During therapeutic plasma exchange when FFP is indicated
3. Reversal of warfarin in an emergency situation, such as before an invasive procedure with active bleeding. However, prothrombin complex concentrates are usually preferable.

Note: Frozen plasma is not indicated for volume expansion or enhancement of wound healing

Cryoprecipitate

1. Hypofibrinogenemia or dysfibrinogenemia with active bleeding
2. Hypofibrinogenemia or dysfibrinogenemia, undergoing an invasive procedure
3. Factor XIII deficiency with active bleeding or undergoing an invasive procedure in the absence of factor XIII concentrate
4. In the preparation of fibrin sealant
5. von Willebrand disease with active bleeding: cryoprecipitate is used in von Willebrand disease only when both of the following are true:
   a. 1-Deamino-8-D-arginine vasopressin is contraindicated, not available, or does not elicit response
   b. Virus-inactivated plasma-derived factor VIII concentrate (which contains von Willebrand factor) is not available

DIC, Disseminated intravascular coagulation; *FFP*, fresh frozen plasma.

developing anti-human leukocyte antigen (HLA) antibodies from granulocyte transfusions, potentially rendering granulocyte transfusions ineffective and complicating possible future hematopoietic cell transplants.[18]

TRANSFUSION MEDICINE: INDICATIONS IN UNIQUE PEDIATRIC POPULATIONS

Hemolytic Disease of the Fetus and Newborn

Hemolytic disease of the fetus and newborn (HDFN) occurs when the mother's immune system recognizes a foreign, paternally inherited antigen on fetal erythrocytes. The incidence of HDFN dramatically declined after the introduction of Rh immune globulin to prevent sensitization of the mother to rheumatic heart disease (RhD). Although the introduction of Rh immune globulin has prevented most cases of HDFN due to RhD sensitization, it has not totally eliminated HDFN due to RhD or reduced HDFN due to other antibodies.

Most significant cases of HDFN are due to antibodies recognizing antigens other than ABO system antigens. These antibodies should be detected in the blood-bank antibody screen of the blood specimen of the pregnant or postpartum woman. Also necessary for diagnosis, the corresponding antigens would be present on fetal or newborn erythrocytes or predicted to be present on fetal erythrocytes based on molecular testing of fetal DNA. The direct antiglobulin test (DAT) of the fetal or newborn's erythrocytes is usually positive, although it can be negative in transfused patients. Although antibody titers can be used to help predict the severity of the disease during pregnancy, they are generally not useful in the newborn. After birth, the severity of the anemia and the resulting hyperbilirubinemia serve as markers for the severity of HDFN. Rates of rise in bilirubin level are most helpful in determining whether an exchange transfusion will be necessary, with increases of 8 to 13 μmol/L/h despite phototherapy indicating that exchange transfusion will likely be necessary.[19]

RBCs transfused in utero to the fetus need to be compatible with the ABO type of the fetus and mother and hence are usually blood group O. They need to lack the antigen(s) to which the mother has made antibodies, and they need to be crossmatch-compatible with her serum. The RBCs should be irradiated to prevent transfusion-associated graft-versus-host disease (TA-GVHD), and cytomegalovirus (CMV)-safe to minimize the risk for transfusion-transmitted CMV. Relatively fresh RBCs also are usually chosen for these transfusions.

Reconstituted whole blood is usually used for neonatal exchange transfusions. The blood is prepared by removing most of the preservative solution from an RBC unit and adding plasma, usually so that the final hematocrit is 40% to 45%.

Neonatal Alloimmune Thrombocytopenia

The pathophysiology of neonatal alloimmune thrombocytopenia (NAIT) is similar to that of HDFN in that both involve immune-mediated attack and destruction of fetal and neonatal blood cells by the mother's immune system. Unlike HDFN, NAIT often affects a woman's first pregnancy. In addition, the antigens involved are due to polymorphisms on platelet-specific proteins. Although a variety of antigens can be implicated, the human platelet antigen-1 (HPA-1) protein is most frequently implicated in Whites, with approximately 70% to 80% of cases being due to women who lack the HPA-1a antigen making antibodies against HPA-1a that is expressed on fetal platelets.[20] When NAIT is suspected, maternal serum can be tested for antibodies to platelet antigens, and the parent's or patient's platelet antigens can be determined by molecular means in which their platelet antigens are indirectly determined from their DNA. An affected infant or fetus may require platelet transfusions. Although random platelets may be of some transient benefit, antigen-negative units are best. Maternal platelets lack the antigen, but because the plasma contains the pathogenic antibody, the platelet unit should be washed before transfusion. Alternatively, antigen-negative units may be available. Indeed, major blood centers usually have HPA-1a-negative units available.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is an intervention in which whole blood is removed from the patient's venous circulation and circulated through a machine to remove carbon dioxide and replenish oxygen before being returned to the patient. This prolonged intervention is reserved for patients with more than 80% mortality risk and those who have been unresponsive to conventional ventilator support and medical treatment but still potentially can recover. In neonates and children, ECMO has become a lifesaving therapy in the treatment of multiple disorders; Table 119.5[21] lists indications for ECMO support in neonates and children. Standardized guidelines for transfusion practice have not been established, resulting in individualized centers establishing their own criteria. In order to prevent thrombosis and platelet activation in the extracorporeal circuit that is composed of extensive tubing, patients are anticoagulated, usually with heparin, resulting in a significant risk of bleeding.[22] Bleeding during ECMO is a common complication and may be caused by any of the following factors necessary for operating the ECMO circuit or resulting from the thrombogenic surface of the circuit: (1) systemic heparinization, (2) platelet dysfunction, (3) thrombocytopenia, (4) other coagulation defects, and (5) nonendothelial cell surface lining the circuitry. It is recommended that hospital transfusion services and ECMO staff be in close communication to agree on local protocols to ensure safe, efficient, and consistent care (Table 119.6 provides an

TABLE 119.5 Indications for Extracorporeal Membrane Oxygenation for Neonates and Pediatric Patients

Neonatal

- Meconium aspiration

TABLE 119.6 Blood Product Protocols for Extracorporeal Membrane Oxygenation

Clinical Scenario	Urgency	Products	Storage
Cardiac arrest	5–10 min	2 units RBCs	<14 days
ECMO circuit disruption	5–10 min	2 units RBCs	<14 days
Progressive septic shock, nonneonate	30 min	2 units RBCs	<10 days
Neonate transferred for ECMO	1–2 h	2 units RBCs 1 unit FFP 1 unit platelets	<10 days
Cardiac ICU	30–60 min	2 units RBCs	<7 days
Gradual respiratory or cardiac failure on conventional support	Hours-days	2 units RBCs	<10 days

ECMO, Extracorporeal membrane oxygenation; *FFP*, fresh frozen plasma; *ICU*, intensive care unit; *RBC*, red blood cell.
Modified from protocols developed at The Children's Hospital of Philadelphia. Friedman DF, Montenegro LM. Extracorporeal membrane oxygenation and cardiopulmonary bypass. In: Hillyer CD, Strauss RG, Luban NLC, eds. *Handbook of Pediatric Transfusion Medicine*. London: Elsevier Academic Press; 2004:181.

example protocol from one institution).[21] Blood products for ECMO are typically ABO-and Rh-specific and crossmatch-compatible for priming. The RBC units for priming circuits are typically relatively fresh, irradiated, and CMV-seronegative and/or leukoreduced.

Trauma

Hemorrhagic shock requiring massive transfusion can occur in children. Prothrombin time (PT), activated partial thromboplastin time (aPTT), and platelet count abnormalities upon emergency room admission are strongly associated with mortality.[23] Transfusion management of a pediatric trauma patient often must be guided by the patient's estimated blood loss and associated signs and symptoms, such as hypotension or tachycardia, and bleeding. A prospective study found that a ratio of 1:1:1 of RBC to plasma to platelet units transfused did not decrease overall mortality but decreased hemorrhagic deaths in trauma patients.[24] The use of such a massive transfusion strategy has not been rigorously tested in pediatric patients. Although some have advocated adopting similar protocols for pediatric trauma centers, this has occurred in only a few places, most likely because there are little data on transfusions in pediatric trauma patients.[25]

Hemoglobinopathies

In patients with sickle cell disease (SCD), chronic transfusion therapy has been shown to reduce the risk for both primary and secondary stroke, by decreasing the hemoglobin S content of the patient's blood, as well as achieving a reduction in sickling, suppression of erythropoiesis, and preventing an increase in blood viscosity.[26,27] The risk for recurrent stroke has been reduced to less than 10% if hemoglobin levels are maintained between 8 and 9 g/dL and hemoglobin S levels below 30%. Simple or partial-exchange transfusion therapy can achieve this goal when performed approximately every 3 to 4 weeks. Chronic erythrocytapheresis has also been used for this therapy with an added mission to mitigate iron overload complications. Chronic transfusion treatment for stroke most times is an indefinite therapy; that is, once the patient is placed on it, cessation is not possible because it has been shown to lead to recurrent stroke.[26] Table 119.2 describes other indications for patients with SCD needing either simple or chronic RBC transfusion therapy. Products for patients with SCD should be screened at a minimum for hemoglobin S and should be leukocyte reduced to reduce the risk for febrile nonhemolytic transfusion reactions and to reduce the risk for HLA alloimmunization, resulting in platelet refractoriness that can complicate possible stem cell transplantation.

In children with SCD, it also is useful to prevent alloimmunization to minor RBC antibodies because most patients with severe SCD will require multiple RBC transfusions during their lifetime. Overall, the SCD patient has higher rates of alloimmunization than other chronically transfused patient groups. The antibodies most frequently produced are against common Rh, Kell, Duffy, and Kidd system antigens. Some sickle cell treatment centers perform thorough phenotype analysis of a patient's red cells before initiating transfusion therapy. This testing helps to reduce the rate of alloimmunization by allowing preferential selection of phenotypically similar units.[28] However, particularly for patients who are not yet alloimmunized, this process remains controversial because phenotypically compatible units may be difficult to obtain and expensive.[29] One common protocol followed for nonalloimmunized patients is pretransfusion phenotypic matching for C, E, and K antigens to reduce the incidence of alloimmunization. Once a patient has developed a red cell antibody, some centers extend matching to additional red cell antigens (Fy, Jk, S) to prevent further alloimmunization. However, care must be taken with some of these strategies as recent studies have found no benefit in alloimmunization rates by providing Rh-matched RBC units from minority donors.[30] The benefits of RBC transfusion therapy in SCD disease must constantly be weighed against the costs (e.g., iron overload, RBC alloimmunization, and increased donor exposure risks). As a result of these issues, some clinicians have proposed that a clinically successful course of transfusions that maintains the hemoglobin S below 30% could, after several years, be transitioned to a strategy of more limited transfusions with a hemoglobin S target of 40% to 50% to reduce the risks for iron overload.[26] Patients with SCD may also be at risk for delayed hemolytic transfusion reactions, the development of autoantibodies, and "hyperhemolytic" syndrome, a phenomenon in which a patient hemolyzes both the native and transfused erythrocytes following RBC transfusion. The mechanism is not well characterized.

Thalassemia

Thalassemia with severe anemia is usually treated with chronic transfusion therapy to improve tissue oxygenation and suppress extramedullary erythropoiesis in the liver, spleen, and bone marrow. This approach mitigates many of the complications caused by the ineffective erythropoiesis. In contrast to chronic transfusion regimens used to treat SCD, most β-thalassemia major patients requiring chronic transfusion therapy start at a very young age. The treatment goals in this population are characterized by (1) increasing oxygen-carrying capacity by anemia correction, (2) preventing progressive hypersplenism, (3) suppressing endogenous erythropoiesis, and (4) reducing gastrointestinal absorption of iron.[31] The target hemoglobin levels are usually 8 to 9 g/dL, where normal growth and development can occur in these patients. Super-transfusion protocols aim for higher target hemoglobin levels (11 to 12 g/dL) to reduce organomegaly from extramedullary hematopoiesis. Iron overload is a complication of this RBC transfusion protocol that cannot be prevented and must be treated with chelation therapy beginning early in childhood. In a recent report from the Centers for Disease Control and Prevention on transfusion complications in thalassemia patients in the thalassemia network in the United States from 2004 to 2012, iron-induced multi-organ dysfunction from transfusion was common despite chelation. Transfusion-transmitted disease pathogens were found in almost one-quarter of those patients monitored and almost 50% of patients experienced transfusion reactions including allergic, febrile nonhemolytic, and hemolytic. RBC alloimmunization was found in 19% of all patients with the most common antigens being E, Kell, and C. Years of transfusion was found to be the strongest predictor of alloantibody formation.[32] Phenotypic-matching protocols are used in some locations to prevent RBC alloimmunization, but data supporting or refuting this practice are scant and further research is needed.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia in children occurs predominantly in young children, with a median age of 3.8 years, and 53% are associated with other immunologic diseases, according to one study in which 74% of the cases had both immunoglobulin G (IgG) and C3d on their surface.[33] Like adult cases, most cases of autoimmune hemolytic anemia in children have antibody reactivity to all RBCs from all donors.

Children also may develop autoimmune hemolytic anemia associated with a Donath-Landsteiner antibody, which is rarely seen in adults. Classically, the Donath-Landsteiner antibody is associated with paroxysmal cold hemoglobinuria, a disease in which patients developed paroxysms of hemoglobinuria following exposure to cold temperatures.[34] However, some children with a Donath-Landsteiner antibody develop symptoms of anemia that are not obviously associated with exposure to cold. The syndrome often develops following an infection such as a respiratory infection.

The Donath-Landsteiner antibody is an IgG antibody that binds erythrocytes, usually recognizing the P antigen, at cold temperatures (<20°C [68°F]) and fixes early components of complement. The fixed complement does not cause significant hemolysis at cold temperatures, but upon warming, the entire complement complex binds and lyses the erythrocytes. Initial testing in the blood bank may be entirely normal or may reveal a positive DAT for C3. The Donath-Landsteiner antibody can be detected only by special testing in which the patient's plasma is incubated with erythrocytes in cold temperatures followed by warm temperatures.

Hematopoietic Cellular Transplant Patients

Transfusion support for HPC transplant patients is similar to that for adult patients, although there are few published studies on transfusion of pediatric HPC transplant patients. RBC transfusions are often not needed in these patients whose hemoglobin level is at least 7 g/dL.[13] While no studies in the modern era have been published on platelet transfusions in these patients, the use of a transfusion trigger of 10,000 platelets/μL, like that used for adults, seems reasonable for those patients without a significant bleeding risk other than thrombocytopenia.

Apheresis

Pediatric apheresis is used for many of the same indications as for adults. However, additional aspects need to be considered in treating pediatric patients. Many children require vascular access through a central vein because the peripheral veins of many children are too small. In addition, peripheral access requires patients to remain seated or reclining with limited arm movement for the procedure duration, and younger patients are often unable to comply with this given that procedures usually last at least 2 hours. During the procedures, children are susceptible to symptomatic hypocalcemia from citrate anticoagulation. For this reason, some pediatric centers use heparin to anticoagulate patients, although prophylactic cation replacement can successfully prevent most symptoms in pediatric apheresis patients.[35] Apheresis procedures subject the patient to volume shifts, which are usually a loss of less than 200 mL of fluid during the procedure and a gain of up to 300 mL at the end of the procedure. The actual fluid shifts depend on the machine, procedure, and parameters for that procedure. In some cases, the volume shifts may be too large to be safe for the patient. In these cases, most machines can be primed with 5% albumin, a RBC unit, or reconstituted whole blood. Using a prime solution, it is possible to minimize fluid shifts so that the patient is effectively volume neutral for the entire procedure. Procedures to accomplish this are usually only available at centers that perform apheresis on relatively large numbers of pediatric patients.

Special Processing and Prevention of Adverse Events in Pediatric Patients

Special processing of blood products is performed more frequently for children than for adults. This is especially true for the preterm infant population, specifically in VLBW infants weighing less than 1500 g and extremely low-birth-weight infants weighing less than 1000 g.

Leukocyte-Reduced Blood Components

Leukoreduced cellular blood products are used in greater than 80% of blood components transfused to children in the United States. The rationale behind the use in pediatric patients has primarily been extrapolated from adult studies. In general, leukoreduction reduces transmission of CMV,[36] decreases HLA alloimmunization,[37] and decreases the frequency of febrile nonhemolytic transfusion reactions. The benefits of leukoreduction for neonates differ from the benefits for older patients. While neonates younger than 4 months of age rarely develop transfusion reactions and rarely become HLA alloimmunized, some neonates, especially premature infants, are at risk for transfusion-transmitted CMV.[36] Additionally, one study of premature infants found that implementation of universal leukoreduction was associated with decreased incidences of retinopathy, prematurity, and bronchopulmonary dysplasia, and decreased length of hospitalization.[38]

Cytomegalovirus-Seronegative Blood Components

Some immunosuppressed pediatric patients, including premature infants, are at risk of significant disease from CMV infection. Transfusion-transmitted CMV can occur because many healthy blood donors have been infected at some point and their leukocytes harbor the virus. Approaches to reduce the risk of transfusion transmission of CMV include transfusion of blood components that test negative for antibodies to CMV (CMV seronegative), are leukoreduced, or both. Although each of these approaches is highly effective, none of these approaches provides zero risk of transfusion-transmitted CMV since blood from donors who were recently infected can lack antibodies to CMV and can contain cell-free virions that are not removed by leukoreduction. The risk of transfusion-transmitted CMV in VLBW infants (<1500 g) is less than 1% when the units are leukoreduced and CMV seronegative.[39] This approach has not been directly compared to using only CMV seronegative or using only leukoreduced units. However, results from older studies found that the residual risk for transfusion-transmitted CMV in adults from CMV seronegative blood components to be between 1% and 3% but current risks are likely lower, and one study found no infants acquiring transfusion-transmitted CMV-from transfusion of CMV seronegative blood components.[40] Leukoreduction is also very effective, reducing the rate of transfusion-transmitted CMV to less than 1% in immunosuppressed patients of all ages.[41] Some have recommended the combined approach of using leukoreduced CMV seronegative units for the prevention of transfusion-transmitted CMV for some of the most at-risk patients.[42] Despite confidence in the safety of using CMV seronegative units, it may not be practical and cost-effective to rely on CMV-seronegative donors as they often constitute less than or equal to one-half of the blood donor pool.

Irradiation

Mortality rates associated with TA-GVHD are as high as 80% to 90%, with no effective treatments. As a result, identifying neonates and children who are immunosuppressed is paramount, so irradiation of cellular components can be performed to prevent this noninfectious serious hazard of transfusion. There are differing expert opinions and practices, and local protocols based on patient populations, available equipment, and best practices at each institution should be followed. The following patients should receive irradiated cellular blood components: (1) premature infants with birth weight less than 1200 g, (2) any child with known or suspected cellular immune deficiency (e.g., severe combined immunodeficiency), (3) any child with significant immunosuppression due to chemotherapy or radiation treatment, (4) any child who receives blood components from blood relatives, and (5) any child who receives HLA-matched or crossmatched platelet components.

Washing

Washing removes the supernatant from RBC or platelet units and is usually performed to reduce the risk of allergic reactions related to plasma. For very young children, washing may also be performed to reduce the concentration of extracellular potassium or to remove anticoagulant-preservative solutions. Washing can also be used to remove pathologic antibodies from a donor unit. Most donor units lack such antibodies. However, if maternal RBC or platelet units are used to treat her newborn with HDFN or neonatal alloimmune thrombocytopenic purpura, respectively, then her plasma would contain the pathogenic antibodies and the units should be washed prior to transfusion. Indeed, because maternal blood contains pathologic antibodies in these settings, its use for these patients is not generally recommended. However, a maternal component may be used because it may be the only component available that lacks the antigen recognized by her antibodies

Volume Reduction

Volume reduction, involving removal of plasma, is primarily used for patients who cannot tolerate the volume of a blood component transfusion, such as some infants with compromised cardiac function. However, it may also be employed for infants and children who receive ABO-mismatched platelet transfusions because several deaths have been reported in the literature of children who have received out-of-group platelets (e.g., O platelet pheresis to A recipient).[43] Not all blood banks volume-reduce such platelets.

Reconstitution of RBCs for Neonatal Exchange Transfusion

During a neonatal exchange, the infant's whole blood is replaced with donor whole blood, which is usually reconstituted whole blood prepared from type-compatible RBCs and plasma. Typically, RBCs less than 5 to 7 days old are used to minimize the concentration of extracellular potassium and, theoretically, provide transfused RBCs that will have maximal in vivo benefit, although this has never been demonstrated. Because of theoretical concerns associated with large volumes of RBC additives transfused to premature infants, nonadditive units are sometimes selected or additives are removed from the RBCs prior to reconstitution. Most blood banks also provide RBC units that are negative for sickle hemoglobin to avoid the rare potential of intravascular sickling. RBC units should be leukoreduced, CMV-seronegative, or both to reduce the incidence of transfusion-transmitted CMV. The RBC unit should also be irradiated to prevent TA-GVHD if the infant is considered at risk of this by local criteria. If irradiated, the RBC or reconstituted whole blood should be irradiated just before the exchange to minimize the liberation of potassium from intracellular stores. Alternatively, the RBC unit can be irradiated prior to volume reduction or washing. The glucose load during an exchange transfusion can be high due to the fact that banked plasma contains added dextrose and because glucose is added to RBC preservative solutions. Hence, glucose levels should be monitored during the first few hours of the exchange.

The goal of most exchanges is to exchange twice the blood volume of the neonate. The volume needed can be calculated based on the fact that the blood volume of a neonate ranges from 100 mL/kg for the most premature to 85 mL/kg for term infants. Usually, one RBC unit is sufficient for a two-volume exchange. The reconstituted whole blood should have a hematocrit of approximately 40% to 50% and must be adequately mixed to maintain the intended hematocrit throughout the exchange transfusion.

The reconstituted whole blood should be transfused through a standard filter and an inline blood warmer. In general, no more than 5 mL/kg of body weight or 5% of the infant's blood volume is to be removed and replaced during a 2 to 5 minutes cycle. The exchange should be performed at a slow pace so as to not cause sudden hemodynamic changes that can result in cerebral blood flow shifts in intracranial pressure, precipitating an intraventricular hemorrhage.[44] A double-volume exchange transfusion typically takes 1.5 to 2 hours.

CHAPTER 120

TRANSFUSION AND APHERESIS SUPPORT FOR SICKLE CELL DISEASE PATIENTS

John P. Manis

Transfusion of red cells in all patients is primarily triggered by the need to increase oxygen delivery to tissues in the setting of blood loss or anemia. For patients with sickle cell disease (SCD), there are additional considerations for transfusion including the need to remove sickle hemoglobin (HbS) containing cells in specific clinical settings. These settings include acute complications (e.g., acute chest syndrome) of SCD or for prophylaxis of vaso-occlusive episodes (VOEs) involving stroke.

Removal or dilution of endogenous HbS red cells by transfusion further benefits patients by preventing further HbS cell sickling and increasing tissue oxygenation, suppressing erythropoietin-induced bone marrow (BM) erythropoiesis, and lengthening the average red cell lifespan. Every transfusion decision, especially in SCD patients must carefully assess risks and benefits regarding when, what, and how to transfuse a red cell component. Patients with SCD experience higher rates of alloimmunization to red cell antigens, iron overload, and also require attention for potential changes in blood viscosity in response to transfusion therapy. Nevertheless, as in all patients with severe hemolytic anemia, selection and modification of red cell components should not delay transfusion in life-threatening emergencies.

Many accepted indications are based primarily on expert consensus, particularly when clinical trials are lacking. Overall, the use of transfusion therapy for SCD is increasing due to expanded indications, increased availability of erythrocytopheresis, and oral chelators to prevent transfusion-associated iron overload.

HEMODYNAMIC CONSIDERATIONS

The interplay of mutations causative for SCD leading to hemoglobin (Hb) polymerization resulting in increased red cell rigidity are described elsewhere (see Chapter 42). One of the main features of SCD is the changes of red cell shape in response in part to delayed polymerization of HbS resulting in a sickle shaped cell. The abnormally shaped red cells are poor at oxygen delivery to tissues and prone to further cell membrane damage resulting in both intravascular and extravascular hemolysis. In addition, the combination of abnormally shaped and damaged cells together with products of hemolysis promotes vasculopathy through endothelial cell dysfunction and vessel occlusion, especially in the capillary vasculature but also in large blood vessels, resulting in ischemic tissue injury, inflammation, and immune dysregulation. The most significant factor that promotes the formation of sickled red cells in SCD is hypoxia, leading to an accumulation of cells in the capillary and venous vasculature. In addition to hypoxia, other factors promote red cell deformation and hemolysis including acidosis and oxidative stress. Moreover, endothelial damage that results from the cycles of ischemic and reperfusion injury results in an environment that promotes further red cell damage and hemolysis. The loss of RBC deformability in SCD is the main factor responsible for the disease morbidity associated VOE.

Blood flow is governed by many factors including hematocrit (Hct), red blood cell shape, oxygenation, plasma proteins, and vascular elasticity. Studies of blood flow (hemorheology) over the past half century have pointed to altered dynamics in patients with SCD, owing largely to increased blood viscosity.[1] In turn, red cells, the largest cellular component of blood, largely govern viscosity with hematocrit and shape being the most important factors. A rise in Hct increases blood viscosity in all vessels and at all flow rates but is especially elevated in low flow vessels such as veins and capillaries. Increased viscosity produces increased resistance and pressure to blood flow, culminating in a drop of oxygen transport. While a drop in oxygen transport due to increased viscosity is seen at relatively high Hb concentrations (>20 g/dL) in cases of secondary polycythemia patients with normal red cells, patients with HbSS show a loss of oxygen delivery at a Hb concentration of about 10 to 12 g/dL. The viscosity of SCD patients is higher than that in patients with healthy red cells at the same hematocrit, which can further increase nearly ten-fold when deoxygenated. Deoxygenation of HbS containing red cells due to both a low flow state and a correspondingly longer time in a hypoxemic environment further promotes increased viscosity and irreversible sickling. Slower flow rates promote increased interactions between blood cells as well as between blood cells and endothelial cells that together with plasma proteins including coagulation and inflammatory factors lead to vaso-occlusion and tissue ischemia and injury. In fact, plasma viscosity increased in SCD is likely also due to these increased acute phase reactants and fibrinogen among other factors. Therefore, increased viscosity dramatically promotes irreversible sickling. However, blood viscosity (and similarly measures of this value alone) may not accurately represent all the forces that contribute to this pathologic process. Additional factors include shear rate, vessel size, and length of blood traversing small vessels. For these reasons, simple transfusion should be avoided in patients with Hb concentrations greater than 10 g/dL. Similarly, in SCD patients that receive transfusion and reach a higher than expected target Hb, phlebotomy to reduce the Hb concentration below 10 g/dL may be considered in some cases, especially in the setting of neurologic compromise.

A variety of additional factors alter the rheology of HbSS red cells, especially when additional genetic defects of Hb production are present. Alpha-thalassemia has been shown to ameliorate the complications seen in patients with HbSS disease, in part due to increased RBC deformability. In contrast, patients with Hb SC disease have increased blood viscosity but RBC deformability is not as severe as that found in SCD. Increased HbF concentrations, either through an inherited sequence modification (Hereditary Persistence of Fetal Hemoglobin [HPFH]), or pharmacologically (i.e., hydroxurea) significantly reduces the number of VOEs and improves the mortality of SCD.[2] In vitro studies have shown that HbF inhibits HbS polymerization, which improves membrane deformability and thus prevents the formation of sickled cells. In addition to red cell intrinsic factors, others affecting the endothelium also adversely influence SCD hemorheology and include products of hemolysis, reactive oxygen species, and nitric oxide concentration.[3] Taken together, one must consider all of these complex factors to plan for transfusion in order to balance the resultant increase of oxygen delivery with the possible increase in viscosity due to the remaining percentage of HbS containing cells.

CLINICAL CONSIDERATIONS FOR TRANSFUSION

Transfusion of healthy donor RBC in SCD serves to both increase oxygen delivery to tissues and to dilute endogenous HbS containing cells. This can be done in an acute setting with the hope of improving end organ damage (e.g., acute chest syndrome, multi-organ failure) or in a prophylactic fashion (e.g., stroke prevention or perioperative settings). Transfusion, however, has not been shown to reverse uncomplicated VOEs consisting primarily of boney pain and correspondingly is not indicated in patients who do not have symptoms of anemia. In those latter cases, transfusion will not improve pain but may prevent further complications of the initial VOE. Clinical trials of when and how to transfuse patients with SCD are few and consequently most clinicians rely on consensus papers and clinical practice (see the box on Indications for Red Cell Transfusion).

INDICATIONS FOR RED CELL TRANSFUSION

Clinical Indication	Simple Transfusion	Exchange Transfusion	Comments
Acute stroke	X	XXX	Exchange transfusion preferred
Primary stroke prevention	X	X	Maintain HbS <30% for at least 1 year
Secondary stroke prevention	X	X	
Severe acute chest	X	XXX	
Recurrent acute chest			Can consider prophylactic transfusion
Operative procedure (preoperatively)	X	X	For general anesthesia >1 h including abdominal surgery, tonsillectomy, orthopedic procedures
Multi-organ failure	X	XXX	
Splenic or hepatic sequestration	XXX	X	
Aplastic crisis	XXX	X	
Chronic transfusion and iron overload		X	
Pregnancy	X		For complicated pregnancy or patients that have been on hydroxycarbamide
Avascular necrosis			Transfuse only for symptomatic anemia
Vaso-occlusive crisis			Transfuse only for symptomatic anemia
Leg ulcers			Transfuse only for symptomatic anemia
Pain			Transfuse only for symptomatic anemia, may help for recurrent painful crises

ACUTE ANEMIA

SCD is a chronic hemolytic anemia that is compensated by increased erythropoiesis and reticulocytosis. Red cell survival is significantly reduced in SCD with HbS cells lasting about two weeks and those with HbF up to 6 weeks. Therefore, stress erythropoiesis is already present even at steady state in untransfused patients with SCD. Any additional insult or burden on red cell production may result in a severe anemia. The net Hb concentration varies significantly among patients with SCD depending on the homeostatic factors controlling erythropoiesis (e.g., erythropoietin, B12, folate) and physiologic adaptation to anemia. Therefore, no single Hb concentration value can define acute anemia, which should be evaluated by comparing the historical peripheral blood Hb concentration of each patient together with a clinical assessment of symptoms of anemia. In addition to the variability of Hb concentrations among patients, each patient has their own variability over time based on factors including hydration, again denoting the need to correlate laboratory values with symptoms. Generally, most SCD patients have a Hb concentration of approximately 8 to 10 g/dL and a Hct of approximately 20% to 30% with reticulocytosis in the range of 3% to 15%. A drop of Hb of 2 to 3 g/dL without a corresponding reticulocytosis and with clinical signs of anemia would warrant transfusion. This is especially important in children where blood flow to the brain increases from birth to early childhood and decreases during adolescence. Children with SCD are at greater risk for silent ischemia that may lead to stroke; therefore, a lower trigger should be strongly considered for transfusion.

Causes of acute anemia include red cell aplasia secondary to parvovirus infection, splenic sequestration or rupture, bleeding, or accelerated hemolysis that may be associated with infection. One of the most important causes of acute anemia in recently transfused SCD patients is delayed hemolytic transfusion reaction (DHTR) (discussed later) that should be evaluated in all such patients. In these clinical settings, there should be prompt consideration to transfuse as it is unlikely that increased erythropoiesis can raise the Hb concentration.

TRANSFUSION FOR COMPLICATIONS OF SICKLE CELL DISEASE

One of the more devastating outcomes in SCD are cerebrovascular accidents. Transfusion for this indication is divided into that for acute stroke and that for prophylaxis for primary or secondary events and are described in detail elsewhere (see Chapter 42). As stroke is a leading cause of morbidity and mortality in SCD, prevention of this complication is a major emphasis of patient care. Many studies have focused on identifying at risk children, with screening regimens using imaging techniques identifying those before neurological injury. The goal for patients at high risk or those with stroke is to decrease the overall percentage of HbS containing cells to at least less than 30%.[4] This is done in patients who cannot for any reason increase the percent of HbF containing cells (failure to respond) or in anticipation of maintenance therapy with hydroxyurea. The length of chronic transfusion therapy for patients is an unresolved question; however, most evidence supports indefinite chronic transfusion therapy. Given the various burdens of chronic transfusion therapy including vascular access, iron overload with simple transfusions and access to transfusion care, stem cell transplantation with matched related donors should be strongly considered. Exchange transfusion remains the mainstay of therapy for many patients in both acute and chronic settings. In acute stroke, simple transfusion is typically initiated given the ease of transfusion and the ability to use simple peripheral access. Exchange transfusion though is the standard of care and has been demonstrated to effectively prevent second strokes better than simple transfusion in children.

Acute chest syndrome (ACS) is another major complication of SCD with multiple underlying causes where exchange transfusion has been widely used to improve outcomes, though randomized control trials are lacking. Exchange transfusion in this setting allows for a rapid reduction of HbS concentrations in blood and an increase in oxygen-carrying HbA to help improve lung tissue perfusion, as the combination of small vessels in the setting of low oxygen tension can trigger sickling and concurrent vaso-occlusion. In children and adult patients with recurrent or frequent episodes of ACS, published reports supporting patients to be treated in chronic transfusion programs have been collected through secondary analyses of the stroke prevention trials including the reduction of painful VOEs. The latter findings underscore the lack of randomized trials to understand the role of transfusion therapy in many complications of SCD including multi-organ failure, priapism, peri-operative transfusion, or pulmonary hypertension. The most unresolved decisions are related to the use of prophylactic transfusions to avoid complications of SCD. For example, in pregnancy where there is an established high rate of SCD-related complications and death, there is varying evidence largely from case series to support prophylactic transfusion. This has supported the view that transfusion should be given "on-demand" for complications with prophylactic transfusion reserved for those patients with known recurrent complications of SCD or high-risk or complicated pregnancy.[5] In these and other settings, transfusion therapy can sometimes be used as an immediate therapy as it can rapidly restore healthy red cells that can subsequently act as a bridge to hydroxyurea or novel agents that may help modify SCD.[6] Correspondingly, for some patients who require a protective bridge therapy during high-risk clinical procedures (e.g., invasive surgery with general anesthesia or before BM transplantation), prophylactic transfusion may protect patients and improve morbidity from ACS or pain.[5]

Red cell transfusion remains a mainstay of therapy for SCD. There is a wide heterogeneity in the need for blood products among patients with SCD, but most patients will receive multiple transfusions over their lifetime. Transfusion can be divided into two general categories: simple transfusion or red cell exchange. Simple red cell transfusion introduces healthy donor red cells without any removal of patient blood in a similar fashion to any other blood transfusion. As in non-SCD patients, the objective is to increase the hemoglobin concentration to correspondingly raise the oxygen-carrying capacity blood. As HbA containing cells are transfused, simple transfusion can easily decrease the concentration of HbS-containing cells to levels sometimes approaching those of an exchange transfusion. For example, a severely anemic SCD patient (e.g., Hb 4 to 6) who has not been transfused in the past three months can decrease their HbS concentration to about 40% from 90% with a target Hb of 8 to 9 g/dL through simple transfusion. This net change approaches results that can otherwise be attained by red cell exchange, which typically takes longer to initiate. For this reason, simple transfusion should be initiated without delay in urgent clinical settings to patients with severe symptomatic anemia given the rapid relative decrease in sickle-containing red cells.

APHERESIS SUPPORTED RED CELL EXCHANGE

While simple transfusions may benefit patients with severe anemia, those who have Hb concentrations between 7 and 9 g/dL, levels frequently seen in SCD patients, require an alternate transfusion strategy. In these cases, patient red cells must be exchanged with healthy donor cells to avoid volume overload or hyperviscosity. Additionally, benefits of red blood cell exchange transfusion (RBCX) occur rapidly; therefore, this approach may be initiated as a bridging therapy for patients that will require hydroxyurea since it can take months to titrate the dose of hydroxyurea and assess its efficacy. Furthermore, an apheretic RBCX results in an isovolemic procedure that benefits patients with volume overload or hemodynamic instability. Manual exchange transfusion involves repeated cycles of phlebotomy followed by transfusion of blood. In these cases, up to 15% of blood may be removed at one time with adjustments made based on the calculated red cell mass and relative volume loss to the patient during the procedure. Manual exchanges are effective, but they are time-consuming and cumbersome, especially for adult patients with large blood volumes. The benefits of manual exchange transfusion include the wide availability of expertise and equipment to perform the procedure, though this is still best performed in dedicated medical units with expertise. An advantage for infants and children is that there is no need for specialized vascular access devices required for the procedure. Nevertheless, manual exchange transfusions can rarely achieve the lowest levels of remaining red cells that contain HbS as the exponential decrease of HbS concentrations requires the exchange of a relatively large blood volume with the concurrent use of significant donor blood. While most recommendations for chronic transfusion programs for stroke prevention is to keep the peak HbS concentration less than 30%, this is a difficult target to achieve. Lastly, manual exchange transfusion involves volume shifts associated with repeated cycles of phlebotomy and transfusion that can compromise hemodynamic stability in some patients.

Automated red blood cell exchange transfusion (aRBCX or erythrocytopheresis) can achieve the lowest concentration of HbS cells remaining in patients with SCD in a safe and rapid fashion. Apheresis instruments rely on the separation of red cells from other components of peripheral whole blood, usually by centrifugation, that can progressively exchange patients' red cells with donor red cells in either a continuous or discontinuous fashion. The overall procedure requires specialized instrumentation, dedicated staff with expertise, and is best managed with transfusion medicine supervision. Automated red cell exchange transfusion requires a relatively large amount of donor blood that is used to gradually deplete patient HbS containing blood.

The large amount of blood exchange during aRBCX requires precise vascular access using either steel intravenous needles or rigid apheresis grade catheters to withstand the intraluminal pressures required to draw and return blood at a fast rate. The use of peripheral veins is the preferred route for achieving vascular access, though this can be difficult for pediatric patients or those patients who have already undergone repeated venipuncture. Peripheral venous access is best achieved by experienced operators, especially those with the capability to use venous imaging techniques including ultrasound. The placement of an apheresis-compatible venous access device can be performed either episodically or implanted for long-term use. The use of catheters or implanted devices is associated with infection or thrombosis and must be carefully tailored for each patient in a chronic aRBCX program. The rate of catheter-related thrombosis has been long recognized to be higher in patients with SCD, though there is no consensus on the use of prophylactic anticoagulation or anti-platelet agents.[7] Lastly, the surgical establishment of an arterio-venous fistula can be considered in patients though there is a higher rate of complications when compared to patients undergoing hemodialysis, and moreover, some patients cannot tolerate the associated hemodynamic alterations.

Several patient-specific parameters are used to program apheresis instruments including the target hematocrit of the patient at the end of the procedure and the percentage of HbS containing cells remaining. There is no consensus on the end Hct target for patients undergoing aRBCX, though consideration is placed on not increasing the end hematocrit above levels resulting in hemodynamic compromise. Concerns for hyperviscosity commonly constrain the choice of end Hct to about 30%, though the loss of HbS containing red cells with the increasing HbA cells partially ameliorate the conditions seen in simple transfusion in SCD.[1] Furthermore, some patients may benefit from higher-end target hematocrits that may suppress endogenous hematopoiesis and potentially increase the time interval between exchange transfusions. Likewise, the target for the fraction of HbS cells remaining (FCR) is commonly set to 30%, largely derived from data surrounding chronic transfusion targets in stroke prevention. Lower targets may be beneficial in some patients, potentially increasing the aRBCX treatment interval. Lowering the FCR, however, significantly increases the number of healthy donor units required for exchange. This is due to the exponential increase in the amount of healthy red cells necessary to remove the reduced number of patient red cells as the aRBCX progresses. This significantly larger amount of donor blood increases red cell unit exposure and may not be possible for patients with highly specified red cell antigen needs. In certain clinical settings such as cardiac surgery, hypothermia and cardiopulmonary bypass and vascular constriction can potentially promote HbS cell sickling. In these cases, FCR values lower than 10% are chosen as targets. Lastly, estimating and entering the actual HbS fraction in the patient immediately prior to apheresis in the instrument algorithm can more precisely calculate and reduce the amount of donor blood necessary for aRBCX.

aRBCX apheresis instruments typically target the removal of red cells that sediment in the central part of the separation gradient, prompting investigation into altered methods of automated exchange to reduce the amount of donor blood needed or to target specific red cell populations.[8] Variations of the procedure to include intermittent aRBCX using a single needle is now available. Other modifications of the procedure include isovolemic hemodilution (or depletion exchange), where patients undergo depletion of peripheral blood to a specified nadir Hct with concomitant infusion of saline or albumin followed by an aRBCX procedure. This patient-specific strategy allows for the use of fewer units of donor red cells and results in an overall higher efficiency procedure. While the blood depletion period of the procedure is relatively brief, consensus criteria for patient selection for this strategy are not determined and may be unfavorable in those intolerant of anemia, hemodynamic alterations, or at higher risk of tissue damage resulting from reduced tissue oxygenation in acute settings (acute stroke or multi-organ failure).

Complications of aRBCX are relatively rare and mostly related to the method of vascular access with more cardiovascular-related complications found in SCD patients. One major concern in the field has been that the increased donor red cell unit exposure directly related to aRBCX may result in an increased risk of alloimmunization. An increase in red cell alloimmunization has not been observed in recent studies of aRBCX in SCD and moreover appears safer when compared to patients receiving episodic transfusion. Other infrequent outcomes associated with exposure to a large number of donor red cell units include allergic reaction, potential infection (e.g., babesia), and non-hemolytic transfusion reactions. A major benefit of aRBCX is the positive effect on iron balance, with a rapid decrease in the ferritin concentration in many patients. As aRBCX may especially affect serum ferritin values in the context of an acute phase reactant, measurement of tissue iron stores (e.g., liver iron concentration by MRI) suggests a relative benefit of aRBCX when compared to simple transfusion with chelation as a means to reduce total iron burden.

PREPARATIVE TRANSFUSION FOR STEM CELL TRANSPLANTATION

Greater attention is being positioned on curative therapies in select patients with SCD. Allogeneic stem cell transplant can deliver curative therapies for a subset of patients with SCD, with the best results and least toxicity achieved with matched sibling transplants. However, fewer than 25% of SCD patients in the United States have a suitable donor available, and fewer than one-third of the remaining patients have an appropriate unrelated matched donor. Allogeneic transplantation is frequently complicated by graft versus host disease, even more so when matched unrelated donors are used as a cell source. In addition, there are higher rates of toxicity that may be related to the conditioning regimens used for transplant, thus leading to the investigation of alternate conditioning-drug regimens. In addition to using allogeneic cells, a large effort has been placed in the use of genetically engineered autologous cells as a graft source for curative transplant. Using autologous cells eliminates the need for donors and eliminates the risk of graft versus host disease. Several approaches including lentiviral mediated gene addition of a modified beta globin gene or shRNA of Bcl11a to induce fetal Hb have encouraging results in clinical trials. Gene editing approaches using CRISPR-based techniques are also being trialed and hold large promise in the field.

The introduction of novel autologous cell therapies in SCD has led to observations involving the potential pathologic effects of the disease on the BM microenvironment and stem cell mobilization.[9] BM harvest was initially used as a source of stem cells in the cell therapies but far fewer than expected stem cells were recovered at harvest, and many patients failed to obtain an adequate gene therapy product. Preclinical studies have demonstrated that chronic tissue injury secondary to vaso-occlusive events can negatively influence the BM microenvironment and potentially even influence transplant outcomes. Strikingly, the transfusion of healthy red cells into a mouse model of SCD reversed many of the pathologic BM changes. These findings may in part explain the fewer numbers of progenitor cells obtained by BM harvest though future work is necessary to understand the role of red cell transfusion in the preparative regimen for transplantation. Presently, most transplant centers perform red cell exchange to keep the HbS less than 30% immediately prior to conditioning. This is done in large part to prevent VOE during the transplant and engraftment period.

One other factor that led to BM being used a cell source in autologous gene therapy is that G-CSF is relatively contraindicated in patients with SCD because it can trigger VOEs. While some patients have successfully weathered peripheral stem cell harvesting for autologous transplants for malignancy, increased morbidity and death have been reported. For these reasons, plerixafor alone has been used to mobilize SCD patients safely and efficiently in preparation for gene therapy. Standard apheresis collection techniques however have yielded fewer than expected stem cells with several consecutive days necessary to achieve target numbers of cells. Altered collection protocols are presently being explored to yield larger stem cell products. Recent studies have indicated that disease severity and increased hospitalization frequency within the preceding year correlated with poor collection yields. Patients undergoing mobilization and collection of stem cells have a preparative red cell exchange to prevent VOEs during the apheresis procedure. Whether red cell exchange improves mobilization and collection remains investigational.

SELECTION OF RED CELL COMPONENTS FOR TRANSFUSION

Red cell component selection in SCD demands careful consideration of both immediate and long-term requirements for safety, as this patient population will require frequent intervention with transfusion throughout their lifetime. Red cell alloimmunization is a major clinical hazard and cause of morbidity and mortality. For this reason, transfusion plans and associated considerations should be worked out well in advanced and individualized for each patient, as this will avoid delays when there is an acute need for red cell transfusion. Transfusion delays specific for SCD patients involve extended red cell antigen testing/matching, attentiveness to transfusion and alloantibody history, and the need to exclude sickle cell trait units. These latter activities may lead to a delay in dispensing red cells and subsequent transfusion; therefore, it is critical to communicate patient needs to blood bank physicians in urgent clinical settings of acute anemia. It is imperative that a detailed transfusion history be obtained from all institutions that have cared for the patient throughout their lifetime. The transfusion history should be obtained on initial hematology intake and updated frequently as key component of the medical record of the patient. Patients should be educated to ask about their transfusion history and to communicate restriction or outcomes to clinicians. This is especially important as transfusion restrictions for SCD patients vary widely among institutions and there is a lack of consensus in current clinical practice.

There are, however, several common considerations in the overall selection of red cell components for SCD. Allergic reactions and anaphylactic reactions to red cell transfusion do not occur more frequently in patients with SCD when compared to other frequently transfused patients; therefore, routine washing or premedication is not required. The use of leukoreduced red cell units leads to far fewer febrile non-hemolytic transfusion reactions that can avoid unnecessary evaluations and admission for SCD patients to exclude infection. Leukoreduction may also reduce alloimmunization to HLA antigens which may interfere with future clinical care. Irradiated blood products are frequently used to prevent transfusion-associated graft versus host disease; however, irradiation does reduce red cell lifespan, which may not be ideal in patients with few available blood units (rare blood type) or those that require chronic transfusion (e.g., RBCX program). Red cell age is a consideration in many transfusion programs and transfusing blood stored longer than 2 or 3 weeks is avoided. Lastly, sickle cell trait blood is excluded from use in SCD patients largely to avoid errors in calculating the percentage of HbS in peripheral blood by electrophoresis. Pathogen testing for red cell parasites (e.g., malaria or babesia) in endemic areas is sometimes performed as SCD patients are at greater risk of complications of infection. Parvovirus B19 is a pathogen that is not inactivated in the serum of most blood products and is particularly hazardous for patients with SCD who rely on stress erythropoiesis for maintenance. The diagnosis of parvovirus B19 infection should be considered in SCD patients with abrupt anemia and reticulocytopenia. Pathogen reduction techniques are under investigation in preventing both transfusion-transmitted infections and in avoiding irradiation by inactivating leukocytes.

TABLE 120.1 Pre-Transfusion Selection of Red Cells

- All patients should have red cell phenotype and preferably genotype in their medical record.
- Complete transfusion history in medical record from all facilities caring for patient.
- For patients who have not developed any alloantibodies: Transfuse red cells that are prophylactically matched for C, c, E, e, and K.
- For patients who have developed alloantibodies: Transfuse red cells excluding clinically significant antigens for which alloantibodies have been identified. Further prophylactic matching should include Fya/Fyb, Jka/Jkb, and S/s, in addition to C, c, E, e, and K.
- Transfusion plan should be documented in advance for patients with alloantibodies.
- Pre-storage leukoreduction to avoid febrile non-hemolytic transfusion reactions.
- Consider using red cell stored fewer than 15 days for patients on chronic transfusion programs.[a]
- Irradiation of red cells to prevent TA-GVHD.[a]

[a] Not evidence-based. RBC units stored longer or irradiated have not been shown to impact clinical outcomes. Decisions should be made based on local blood supply.
TA-GVHD, Transfusion-associated graft-versus-host-disease.

RED CELL ANTIGEN MATCHING

Alloimmunization resulting from mismatched RBC antigen is of enormous concern and consequence in individuals with SCD. Alloimmunization is far more common in SCD and commonly occurs if red cells are not fully matched for RH and Kell antigens. Patients with SCD are heavily allo-immunized as a group with prevalence estimates ranging from 10 to 66%.[10] There are multiple explanations for this higher than expected alloimmunization prevalence with a major factor being the red cell antigen differences between those in the healthy blood donor population and SCD patients. For example, African-Americans as a group are more likely to lack C, E, and K antigens, and accordingly, antibodies toward these antigens were the most common ones detected in SCD patients. However, even approaches to ethnically match donors and recipients have not eliminated alloimmunization. Other factors in SCD including those related to hemolysis or inflammation are associated with increased alloimmunization. Elevated free heme as a result of hemolysis is associated with an increased rate of alloimmunization.[10] Hemolysis can affect many immune cell functions and networks and therefore augment immune responses such as allo-immunization.[11] Free heme can also activate neutrophils and macrophages and enhance endothelial cell injury which again is associated with enhanced immune response. Pro-inflammatory markers including Il-6 and gamma interferon have been detected in SCD patients at higher levels and are associated with higher rates of alloimmunization patients with SCD, though the exact mechanisms affecting alloimmunization remain unknown.[12]

Various strategies of red cell antigen matching have been devised to prevent alloimmunization in SCD (Table 120.1). Expert panels have long recommended additional (to the universal ABO and D) prophylactic matching to include Rh (C, E or C/c, E/e), and K in patients with SCD.[5] Extending the crossmatch to other common red cell antigens including Fya/Fyb, Jka/Jkb, and S/s can further reduce alloimmunization though finding sufficient numbers of compatible units of red cells poses a significant challenge. Therefore, extended matching beyond Rh and K is usually reserved for those patients that have already formed a red cell antibody and are therefore at higher risk of forming additional alloantibodies. To enable antigen matching, an extended red cell antigen profile should be obtained in all SCD patients and be placed in the medical record. Traditional serologic testing for red cell antigen phenotypes has been largely supplanted by molecular analysis using DNA methods. Genotyping offers higher accuracy and additional information including detecting mutations in the GATA motif of the Duffy blood group genes that can identify patients that are not at risk for forming anti-Fy^b. Extended sequence analysis has yielded a large amount of sequence variation in all blood group antigens, but especially in those related to Rh.[13] A large amount of diversity exists in the Rh genes of patients of African descent. The two highly homologous Rh loci, *RHD* and *RHCE*, resulted from gene duplication and have resulted in variant RHD and RHCE alleles. Only a few frequent variants such as weak or partial D can be detected serologically; consequently, only DNA sequencing can distinguish specific genotypes. The sequence information can be used to understand alloimmunization to Rh antigens in SCD patients and sometimes can be used in matching donor red cell units. Cost and the ability to recruit the large number of blood donors now underrepresented in most blood banks have largely hindered extended genotype-guided red cell antigen matching, though this goal is currently being examined.[5]

COMPLICATIONS OF TRANSFUSION THERAPY

Alloimmunization is a major clinical problem for SCD patients with an accompanying burden to blood banking resources to find compatible blood in a timely fashion. Delays of finding appropriate blood can lead to poor outcomes. Given the relatively high prevalence of alloimmunization in SCD, most reactions to transfusion, including anaphylactic require close examination to exclude antibodies against RBC antigens. Identification of alloantibodies is crucial in preventing future hemolytic reactions that typically present clinically as a DHTR. Rapid determination of antigen specificity is necessary as most alloantibodies are short lived and proper documentation in the patient record is necessary to prevent DHTR. The presentation of patients with suspected DHTR is variable and is under-reported due to the lack of recognition.[14] Recent consensus guidelines have defined DHTR as a significant drop in hemoglobin within 21 days of transfusion, without an alternative cause. Associated evidence including an increase in the HgbS percentage and anemia can support the diagnosis of DHTR. Frequently, DHTR present with vaso-occlusive crises including bony pain or ACS, anemia, hemoglobinuria, and elevated markers of hemolysis in the blood (e.g., bilirubin or lactate dehydrogenase). Detection of alloantibodies by red cell screening assays yields results in as few as a third of cases. Assays to detect alloantibodies should be repeated over weeks after the transfusion to detect those with altered temporal kinetics. Therefore, a high degree of vigilance must be maintained to diagnose DHTR in all SCD patients undergoing transfusion.

Management of individuals with suspected DHTR is largely supportive and should focus on the treatment of the anemia and hydration. Transfusion should be avoided unless necessary and preferably after the inciting red cell antigen is identified to enable avoidance when selecting red cell units. In patients with severe DHTR, prophylactic immunosuppression with corticosteroids or intravenous immune globulin can be considered. Treatment with rituximab is investigational and may cause prolonged immunosuppression with associated morbidity. One of the most serious and potentially fatal complications of transfusion-associated hemolysis is hyperhemolysis or bystander hemolysis. Hyperhemolytic transfusion reactions (HHTR) entail alloimmune hemolysis of transfused red cells together with hemolysis of endogenous patient RBCs. HHTR is usually defined as a DHTR where the Hb concentration falls below the pretransfusion value. The mechanism of HHTR is poorly understood; however, there is increasing evidence that the complement pathway is integral in sustaining this syndrome. Immune complexes of alloantibodies and products of hemolysis can activate the classical and alternate complement pathways, respectively.[15] Treatment of HHTR is similar to that of DHTR with immunosuppression using glucocorticoids and supportive care. In steroid-refractory cases of HHTR, recent reports have suggested that complement inhibition using a monoclonal antibody targeting C5 may be helpful. Eculizimab treatment carries the associated risk of meningococcal infection, and anti-meningococcal prophylaxis may be considered. Given the high degree of hemolysis and the overall stress on the erythropoietic lineage, erythropoietin, iron, B12, and folate should be optimized to support the production of red cells. Mortality associated with HHTR has been estimated to be approximately 5% to 10%, and patients that have a history of HHTR are likely to have subsequent episodes of the syndrome. For this reason, hematopoietic stem cell transplant is sometimes considered.

IRON OVERLOAD

Iron overload is the most frequent result and complication of transfusion therapy. Identification and management of iron overload is discussed in detail elsewhere (see Chapters 37, 41, and 43). Iron overload is a prevalent problem in all patients undergoing chronic transfusion. Each milliliter of red cells contains up to one mg of iron, with a significant burden quickly accumulating especially in patients on chronic transfusion therapy. Excess iron stores cannot be eliminated, and chelation therapy is needed to remove the large amounts of iron present in transfused SCD patients. Interestingly, iron accumulates mostly in the liver in SCD in contrast to tissues such as the heart or endocrine organs in patients with thalassemia. Management of iron overload in SCD requires careful documentation of blood transfusion with a cumulative count in the patient record. Serial assessment of ferritin with tissue iron stores in the liver and sometimes the heart should be performed. Although patients undergoing chronic aRBCX treatment typically have a negative iron balance, not all have positive responses and tissue stores should be periodically examined.

PART XI HEMOSTASIS AND THROMBOSIS

CHAPTER 121

OVERVIEW OF HEMOSTASIS AND THROMBOSIS

James C. Fredenburgh and Jeffrey I. Weitz

INTRODUCTION

Hemostasis preserves vascular integrity by balancing the physiologic processes that maintain blood in a fluid state under normal circumstances and prevent excessive bleeding after vascular injury. Preservation of blood fluidity depends on an intact vascular endothelium, and a complex series of regulatory pathways that maintain platelets in a quiescent state and keep the coagulation system in check. In contrast, arrest of bleeding requires rapid formation of hemostatic plugs at sites of vascular injury to prevent severe hemorrhage. Perturbation of hemostasis can lead to bleeding or thrombosis. Bleeding will occur if there is failure to seal vascular leaks either because of defective hemostatic plug formation, or because of premature breakdown of the plugs. In contrast, thrombosis may occur if prothrombotic stimuli are unregulated, or if thrombus resolution is attenuated.

Thrombosis can occur in arteries or veins and is a major cause of morbidity and mortality. Arterial thrombosis is the most common cause of acute coronary syndrome, ischemic stroke, and limb gangrene, whereas thrombosis in the deep veins of the leg leads to postthrombotic syndrome and pulmonary embolism, which can be fatal.

Most arterial thrombi form on top of disrupted atherosclerotic plaques, because plaque rupture exposes thrombogenic material in the plaque core to the blood.[1–3] This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that temporarily or permanently occludes blood flow. Temporary occlusion of blood flow in coronary arteries may trigger unstable angina, whereas persistent obstruction causes myocardial infarction. The same processes can occur in the cerebral circulation, where temporary arterial occlusion may manifest as a transient ischemic attack, and persistent occlusion can lead to a stroke. Likewise, critical limb ischemia can occur if there is superimposed thrombosis on ruptured atherosclerotic plaques in the major arteries supplying blood to the lower extremities.[1]

In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption.[3,4] Although they can develop after surgical trauma to veins, or secondary to indwelling venous catheters, they usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses, where there is stasis. Sluggish blood flow in these veins reduces the oxygen supply to the avascular valve cusps. Hypoxemia induces endothelial cells lining the valve cusps to become activated and express adhesion molecules onto their surfaces. Tissue factor–bearing leukocytes and microparticles adhere to these activated cells and induce coagulation. Impaired blood flow exacerbates local thrombus formation by reducing clearance of activated clotting factors and consumption of regulatory molecules. These responses constitute the three axes of Virchow's triad associated with development of thrombosis: stasis, hypercoagulability of the blood, and activation or disruption of the endothelium. A further complication of thrombosis is embolism, where venous or arterial thrombi can dislodge and travel to the lungs, brain, or other organs to produce pulmonary embolism, ischemic stroke, or systemic embolism, respectively.[1,4]

Arterial and venous thrombi contain platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear on this side of the circulatory system. In contrast, venous thrombi, which form under low shear conditions, contain relatively few platelets, and consist mostly of fibrin and trapped red blood cells. Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi appear red.

The antithrombotic drugs used for prevention and treatment of thrombosis target components of thrombi and include antiplatelet drugs, which inhibit platelets; anticoagulants, which attenuate coagulation; and fibrinolytic agents that induce fibrin degradation (see Chapter 143). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents, although in the acute setting, strategies often include anticoagulants and fibrinolytic agents. When arterial thrombi are occlusive and rapid restoration of blood flow is imperative, mechanical and pharmacologic methods enable thrombus extraction, compression, or degradation. Parenteral anticoagulants are often given in conjunction with reperfusion therapy to prevent re-occlusion and clotting on guidewires and catheters. Anticoagulants may also be given for secondary prevention in patients with arterial thrombosis. Thus, when compared with placebos in stabilized patients with acute myocardial infarction, low-dose rivaroxaban administered on top of antiplatelet therapy reduced recurrent ischemic events and stent thrombosis.[5] Likewise, dual pathway inhibition with aspirin plus low-dose rivaroxaban is superior to either agent alone for prevention of major adverse cardiac and limb events in patients with coronary artery or peripheral artery disease.[6,7]

Anticoagulants are the mainstay for prevention and treatment of venous thromboembolism because fibrin is the predominant component of venous thrombi (see Chapter 143). Antiplatelet drugs are less effective than anticoagulants because of the limited platelet content of venous thrombi. Nonetheless, aspirin is as effective as rivaroxaban for extended thromboprophylaxis after hip or knee arthroplasty.[8] Selected patients with venous thromboembolism benefit from fibrinolytic therapy—for example, patients with massive pulmonary embolism achieve more rapid restoration of pulmonary blood flow with systemic, or catheter-directed, fibrinolytic therapy than with anticoagulant therapy alone. Certain patients with extensive deep vein thrombosis in the iliac and/or femoral veins may also have a better outcome with catheter-directed fibrinolytic therapy, and/or mechanical thrombus extraction in addition to anticoagulants.

This chapter provides an overview of hemostasis and thrombosis by highlighting the processes involved in platelet activation and aggregation, blood coagulation, and fibrinolysis.

HEMOSTATIC SYSTEM

The major components of the hemostatic system are the vascular endothelium, platelets, and the coagulation and fibrinolytic systems. The complex interplay between cellular and soluble factors is termed immunohemostasis. Although these highly integrated processes maintain normal hemostasis under physiological conditions, their dysregulation can lead to pathological responses (see box on Immunohemostasis).

Vascular Endothelium

A monolayer of endothelial cells lines the intimal surface of the circulatory tree and separates the blood from the prothrombotic subendothelial components of the vessel wall (see Chapter 122). As such, the vascular endothelium encompasses about 10^{13} cells and covers a vast surface area. Rather than serving as a static barrier, the healthy vascular endothelium is a dynamic organ (Fig. 121.1) that actively regulates hemostasis by inhibiting platelets, suppressing coagulation, promoting fibrinolysis, and modulating vascular tone and permeability.[3] Defective vascular function can lead to bleeding if the endothelium becomes more permeable to blood cells, if vasoconstriction does not occur, or if premature degradation of hemostatic plugs reopens repaired vasculature.

Platelet Inhibition

Endothelial cells synthesize prostacyclin and nitric oxide and release them into the blood.[11] These agents not only serve as potent vasodilators, but also inhibit platelet activation and subsequent aggregation by stimulating adenylate cyclase and increasing intracellular levels of cyclic adenosine monophosphate (cAMP). In addition, endothelial cells express CD39 on their surfaces, a membrane-associated ecto-adenosine diphosphatase (ADPase). By degrading adenosine diphosphate (ADP), which is a platelet agonist, CD39 attenuates platelet activation.

Anticoagulant Activity

Intact endothelial cells play an essential part in the regulation of thrombin generation through a variety of mechanisms. Endothelial cells produce heparan sulfate proteoglycans, which bind circulating antithrombin and accelerate the rate at which it inhibits thrombin and other coagulation enzymes. Tissue factor pathway inhibitor (TFPI), a naturally occurring inhibitor of coagulation, binds heparan sulfate on the endothelial cell surface.[12] Administration of heparin or low-molecular-weight heparin (LMWH) displaces glycosaminoglycan-bound TFPI from the vascular endothelium, and released TFPI may contribute to the antithrombotic activity of these drugs.

Endothelial cells regulate thrombin generation by expressing thrombomodulin and endothelial cell protein C receptor (EPCR) on their surfaces. Thrombomodulin binds thrombin and alters its substrate specificity such that thrombin no longer acts as a procoagulant but becomes a potent activator of protein C (see Chapter 125). Activated protein C (APC) serves as an anticoagulant by degrading activated factor V and factor VIII (factor Va and VIIIa, respectively), key cofactors involved in thrombin generation. Protein S acts as a cofactor in this reaction, and EPCR enhances this pathway by binding protein C and presenting it to the thrombin–thrombomodulin complex for activation. In addition to its role as an anticoagulant, APC also regulates inflammation and preserves the barrier function of the endothelium.[13]

Fibrinolytic Activity

The vascular endothelium promotes fibrinolysis by synthesizing and releasing tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA), which initiate fibrinolysis by converting plasminogen to plasmin (see Chapter 125). Endothelial cells in most vascular beds synthesize t-PA constitutively and release it in response to stimuli such as thrombin or bradykinin. In contrast, perturbed endothelial cells produce u-PA in the settings of inflammation and wound repair.

IMMUNOHEMOSTASIS

The hemostatic system is not the sole mechanism through which the vasculature is protected from disruption. There is overwhelming evidence that inflammation plays an equally important part and that the two processes are tightly integrated and mutually dependent.[3,9] The terms immunohemostasis and thromboinflammation have been coined to capture this interplay. The inflammatory axis can be integrated into the cell-based model of hemostasis because leukocytes, platelets, and the endothelium are critical components of both processes. For example, tissue factor expression by monocytes is upregulated in response to inflammatory cytokines. The reductionist view of hemostasis and inflammation considers these pathways in isolation. However, it is now apparent that inflammation plays an integral part in stroke, deep-vein thrombosis, and myocardial infarction, processes previously attributed to dysregulation of hemostasis.[10] In agreement with their similar protective and reparative roles, both thrombosis and inflammation are initiated in response to tissue damage or pathogen infection.

Platelets provide an obvious link between the hemostatic and immune systems because they respond to bacterial or viral infection, as well as to ischemia and cancer. Because of their proximity, platelets are among the first cells to arrive at sites of injury where they interact with leukocytes and endothelial cells. Upon activation, platelets expose ligands that mediate their interaction with immune cells. Such ligands include P-selectin, intercellular adhesion molecule (ICAM)-2, macrophage-1 antigen (MAC-1), and CD40L. Furthermore, platelets express toll-like and Fc receptors and release soluble effectors such as cytokines, chemokines and platelet factor 4. Platelets also link the complement system to the coagulation and immune systems because platelets bind C3b via P-selectin and C3 via GPIb-alpha, and because they release bactericidal mediators such as thrombocidin. Consequently, platelets link hemostasis with innate and adaptive immunity.

Leukocytes provide another link in the thromboinflammation axis. Activated platelets and endothelial cells express P-selectin on their surface. Leukocytes bind P-selectin via P-selectin glycoprotein ligand-1 (PSGL-1), a counter receptor that is constitutively expressed on their surface. This interaction results in the formation of platelet-leukocyte aggregates and the tethering of leukocytes to the endothelium, interactions that promote the release of pro-inflammatory cytokines, reactive oxygen species, and proteolytic enzymes and facilitate neutrophil transmigration to sites of inflammation. Therefore, leukocytes contribute to innate immunity.

Leukocytes also contribute to coagulation. Activated monocytes express tissue factor, which triggers coagulation via the extrinsic pathway. Activated neutrophils undergo NETosis, which involves programmed release of neutrophil extracellular traps (NETs) that originate from decondensed chromatin and consist of DNA, histones, and metalloproteases such as myeloperoxidase (MPO) and elastase. The mesh-like structure of NETs provides a scaffold for platelet adhesion where histones can activate them and the DNA in NETs triggers coagulation via the contact system. Confirmation of the role of neutrophils and NETs in coagulation comes from the observations that neutrophil depletion or DNase administration attenuates thrombosis in murine models.

Enhanced understanding of thromboinflammation has identified new disease pathways and has revealed novel targets for directed therapy. The hypercoagulability in patients with novel coronavirus disease (COVID-19) illustrates the reciprocal and tight integration of thrombosis and inflammation (see Chapter 153). Such integration is also evident in chronic inflammatory diseases and explains why patients with inflammatory bowel disease, systemic lupus erythematosus and rheumatoid arthritis are at higher risk for thrombosis than those without these conditions. These revelations have prompted routine thromboprophylaxis for hospitalized patients with COVID-19, the use of global Janus kinase (JAK) inhibitors to attenuate inflammation in patients with rheumatic diseases, and the evaluation of novel agents such as soluble thrombomodulin for treatment of DIC.

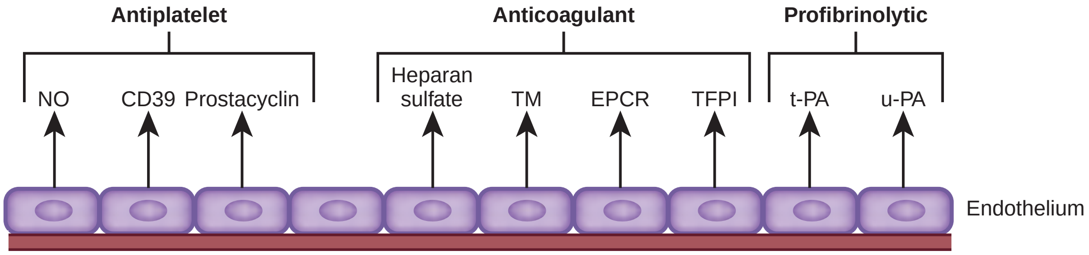

Figure 121.1 THE ANTITHROMBOTIC FUNCTIONS OF THE ENDOTHELIUM. The healthy endothelium has *(left)* antiplatelet activity because of synthesis and release of prostacyclin and nitric oxide *(NO)* and expression of CD39, a membrane-associated ectoADPase; *(center)* anticoagulant activity because of heparan sulfate proteoglycan-mediated activation of antithrombin and expression of thrombomodulin *(TM)* and endothelial protein C receptor *(EPCR)*, which are involved in protein C activation, and surface-bound tissue factor pathway inhibitor *(TFPI)*; and *(right)* profibrinolytic activity because of release of tissue and urokinase-type plasminogen activator (t-PA and u-PA, respectively).

Endothelial cells also produce type 1 plasminogen activator inhibitor (PAI-1), the major inhibitor of both t-PA and u-PA. Therefore, net fibrinolytic activity depends on the dynamic balance between the release of plasminogen activators and PAI-1. Fibrinolysis is localized to the endothelial cell surface because these cells express annexin II, a coreceptor for plasminogen and t-PA that promotes their interaction. Therefore, healthy vessels actively resist thrombus formation and help maintain platelets in a quiescent state.

Vascular Tone and Permeability

In addition to synthesizing potent vasodilators, such as prostacyclin and nitric oxide, endothelial cells also produce a group of counter-regulatory peptides known as endothelins that induce vasoconstriction. Endothelial cell permeability is influenced by the connections that join endothelial cells to their neighbors. Macromolecules traverse the endothelium via patent intercellular junctions, by endocytosis, or through transendothelial pores. Vasodilatation, severe thrombocytopenia, and high doses of heparin can increase endothelial permeability, which may contribute to bleeding. Bradykinin, generated through degradation of high molecular weight kininogen by kallikrein, also induces vascular leakage and inflammation. APC combats these effects by attenuating inflammation and vascular permeability, thereby enhancing the barrier function of the endothelium.

Platelets

Platelets are anucleate cellular particles released into the circulation after programmed fragmentation of bone marrow megakaryocytes (see Chapter 123). Because they are anucleate, platelets have limited capacity to synthesize proteins. Consequently, platelet protein composition is determined by the parent cell as well as by those factors endocytosed from the circulation. Thrombopoietin, a glycoprotein synthesized in the liver and kidneys, regulates megakaryocytic proliferation and maturation as well as platelet production. Once they enter the circulation, platelets have a life span of 7 to 10 days.

Damage to the intimal lining of the vessel exposes the underlying subendothelial matrix. Platelets home to sites of vascular disruption and adhere to the exposed matrix proteins (see Chapter 124). Adherent platelets undergo activation and not only release substances that recruit additional platelets to the site of injury, but also promote thrombin generation and subsequent fibrin formation (Fig. 121.2). A potent platelet agonist, thrombin amplifies platelet recruitment and activation. Activated platelets then aggregate to form a plug that seals the leak in the vasculature.[14] An understanding of the steps in these highly integrated processes helps pinpoint the sites of action of antiplatelet drugs, and rationalizes the utility of anticoagulants for the treatment of arterial thrombosis and venous thrombosis.

Adhesion

Platelets adhere to von Willebrand factor (vWF) and collagen that originate from endothelial cells and the subendothelium, respectively. The platelet monolayer promotes thrombin generation and subsequent fibrin formation. These events depend on constitutively expressed receptors on the platelet surface, α2β1 and glycoprotein (GP) VI, which bind collagen, and GPIbα and GPIIb/IIIa (αIIbβ3), which bind vWF. The platelet surface is crowded with receptors, but those involved in adhesion are the most abundant: every platelet has about 40,000 to 80,000 copies of GPIIb/IIIa and 25,000 copies of GPIbα. Receptors cluster in cholesterol-enriched subdomains, which render them more mobile, thereby increasing the efficiency of platelet adhesion and subsequent activation (see Chapter 124).

Under low shear conditions, such as in the venous circulation, collagen can capture and activate platelets on its own. Captured platelets undergo cytoskeletal reorganization that causes them to flatten and adhere more closely to the damaged vessel wall. Under high shear conditions in the arterial system, however, collagen and vWF must act in concert to support optimal platelet adhesion and activation. vWF synthesized by endothelial cells and megakaryocytes assembles into multimers that range from 550 to over 10,000 kDa. When released from storage in the Weibel-Palade bodies of endothelial cells or the α-granules of platelets, most of the vWF enters the circulation, but the vWF released from the abluminal surface of endothelial cells accumulates in the subendothelial matrix, where it binds collagen via its A3 domain. This surface-immobilized vWF can simultaneously bind platelets via its A1 domain. In contrast, circulating vWF does not react with unstimulated platelets. This difference in reactivity likely reflects vWF conformation; circulating vWF is in a coiled conformation that prevents access of its platelet-binding domain to vWF receptors on the platelet surface, whereas immobilized vWF assumes an elongated shape that exposes its A1 domain. Shear forces at sites of vascular injury also unfold vWF, thus contributing to the abundance of platelets in arterial thrombi. In this extended conformation, large vWF multimers serve as the molecular glue that tethers platelets to the damaged vessel wall with sufficient strength to withstand higher shear forces.[15] Large vWF multimers provide additional binding sites for collagen and heighten platelet adhesion because platelets have more vWF receptors than collagen receptors.

The size of the vWF multimers is regulated by ADAMTS13, a circulating metalloprotease and member of *A D*isintegrin *A*nd *M*etalloprotease with *T*hrombo*S*pondin type 1 repeats (ADAMTS) family.[15] Synthesized in hepatic stellate cells and found in other cells including endothelial cells, megakaryocytes and platelets, ADAMTS13 is secreted into plasma as a constitutively active enzyme. ADAMTS13 cleaves vWF, thereby preventing accumulation of ultra large multimers. Such cleavage is essential for normal hemostasis. Thus, deficiency of ADAMTS13 because of autoantibody formation or inherited mutations leads to thrombotic thrombocytopenic purpura (see Chapter 132), which is characterized by microvascular occlusion by platelet aggregates induced by ultra large vWF multimers.

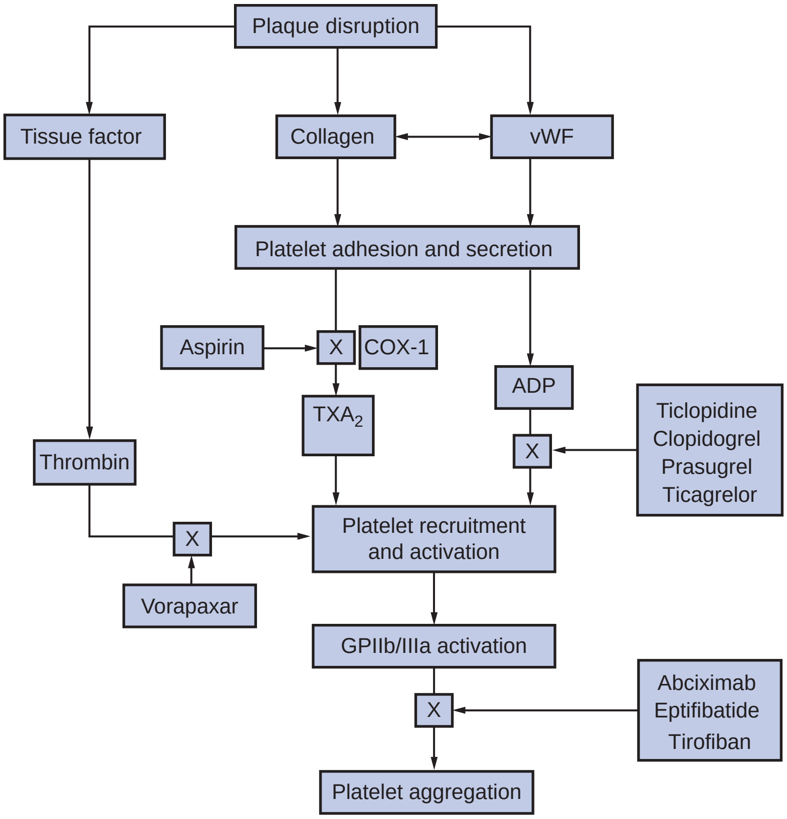

Figure 121.2 SITES OF ACTION OF ANTIPLATELET DRUGS. Aspirin inhibits thromboxane A2 *(TXA2)* synthesis by irreversibly acetylating cyclooxygenase-1 *(COX-1)*. Reduced TXA2 release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block P2Y12, a key ADP receptor on the platelet surface, whereas ticagrelor is a reversible inhibitor of P2Y12. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen and von Willebrand factor *(vWF)* binding to activated glycoprotein *(GP)* IIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting protease activated receptor-1 *(PAR-1)*, the major thrombin receptor on platelets. *ADP*, Adenosine diphosphate.

Platelet adhesion to collagen or vWF results in platelet activation and secretion, the next steps in platelet plug formation.

Activation and Secretion

Adhesion to collagen and vWF initiates signaling pathways that result in platelet activation. These pathways induce cyclooxygenase-1 (COX-1)–dependent synthesis and release of thromboxane A2 and trigger the release of ADP from storage granules. Thromboxane A2 is a potent vasoconstrictor, and like ADP, locally activates ambient platelets and recruits them to the site of injury. This process results in expansion of the platelet plug. To activate platelets, thromboxane A2 and ADP must bind to their respective receptors on the platelet membrane. The thromboxane receptor (TP) is a G protein–coupled receptor that is found on platelets and on the endothelium, which explains why thromboxane A2 induces vasoconstriction as well as platelet activation.[16] ADP interacts with a family of G protein-coupled receptors on the platelet membrane. Most important of these is P2Y12, which is the target of the thienopyridines, but P2Y1 also contributes to ADP-induced platelet activation, and maximal ADP-induced platelet activation requires activation of both receptors. A third ADP receptor, P2X1, is an adenosine triphosphate (ATP)–gated calcium channel. Platelet storage granules contain ATP as well as ADP; ATP released during the platelet activation process may contribute to the platelet recruitment process in a P2X1-dependent fashion.

Although TP and the various ADP receptors signal through different pathways, they all trigger an increase in the intracellular calcium concentration in platelets. This, in turn, induces shape change via cytoskeletal rearrangement, granule mobilization and release, and subsequent platelet aggregation. Activated platelets promote coagulation by cycling phosphatidylserine from the inner membrane bilayer to the outer layer. Surface exposure of this anionic phospholipid is essential for assembly of coagulation factor complexes (see Chapter 125). Once assembled, these clotting factor complexes trigger a burst of thrombin generation and subsequent fibrin formation. In addition to converting fibrinogen to fibrin, thrombin amplifies platelet recruitment and activation, thus promoting expansion of the platelet plug. Thrombin binds to protease-activated receptor (PAR) types 1 and 4 (PAR1 and PAR4, respectively) on the platelet surface and cleaves their extended amino-termini, thereby generating new amino-termini that serve as tethered ligands that bind internally and activate the receptors (Fig. 121.3). Whereas low concentrations of thrombin cleave PAR1, PAR4 cleavage requires higher thrombin concentrations.[17] Cleavage of either receptor triggers platelet activation.

In addition to providing a surface on which clotting factors assemble, activated platelets also promote fibrin formation and subsequent stabilization by releasing factor V, factor XI, fibrinogen, and factor XIII (see Chapters 124 and 125). Thus, there is coordinated activation of platelets and coagulation, and the fibrin network that results from thrombin action helps anchor the platelet aggregates at the site of injury. Activated platelets also release adhesive proteins, such as vWF, thrombospondin, and fibronectin, which augment platelet adhesion at sites of injury, as well as growth factors, such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β), which promote wound healing. Platelet aggregation is the final step in the formation of the platelet plug.

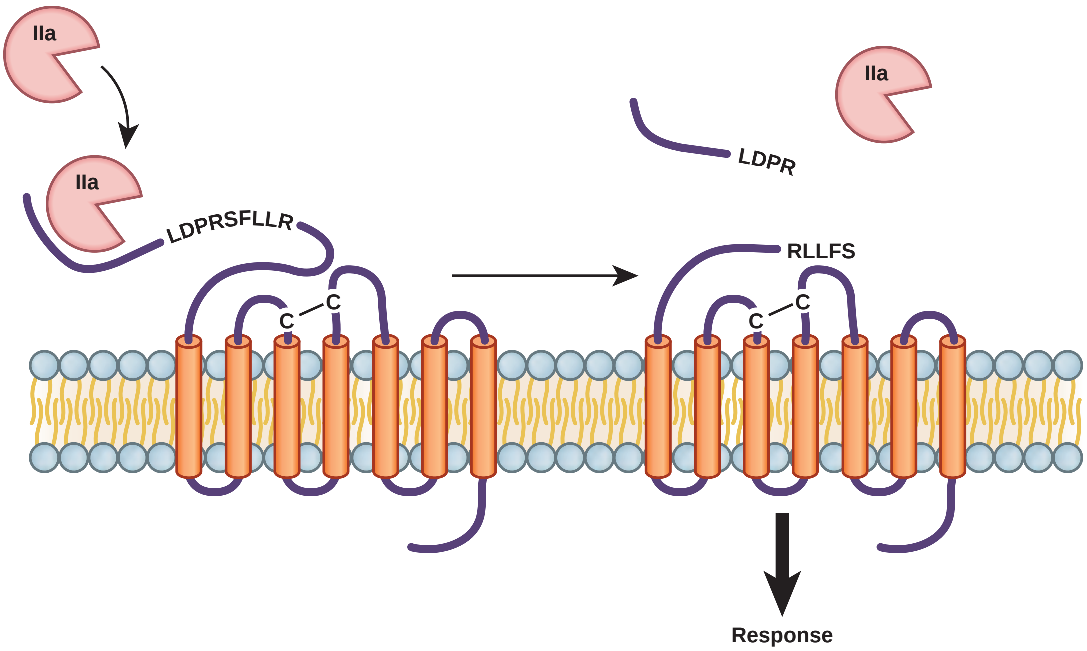

Figure 121.3 ACTIVATION OF PROTEASE-ACTIVATED RECEPTOR (PAR)-1 BY THROMBIN. Thrombin (IIa) binds to the amino terminus of the extracellular domain of PAR-1 where it cleaves a specific peptide bond. Cleavage of this bond generates a new amino-terminal sequence of Ser-Phe-Leu-Leu-Arg (SFLLR) that acts as a tethered ligand and binds to the body of the receptor, thereby activating it. Thrombin then dissociates from the receptor. Analogues of the first five or six amino acids of the tethered ligand sequences, known as thrombin receptor agonist peptides, can independently activate PAR-1.

Aggregation

GPIIb/IIIa mediates platelet-to-platelet linkages that result in the formation of clumps of platelets. On nonactivated platelets, GPIIb/IIIa exhibits minimal affinity for its ligands. Upon platelet activation, GPIIb/IIIa undergoes a conformational transformation, which reflects transmission of inside-out signals from its cytoplasmic domain to its extracellular domain.[18] This transformation enhances the affinity of GPIIb/IIIa for its ligands, fibrinogen, and, under high shear conditions, vWF (see Chapter 124). Cryptic Arg-Gly-Asp (RGD) peptide sequences located in fibrinogen and vWF, as well as a platelet-binding Lys-Gly-Asp (KGD) sequence in fibrinogen, mediate their interaction with GPIIb/IIIa. When subjected to high shear, circulating vWF elongates and exposes its platelet-binding domain, which enables its interaction with the conformationally activated GPIIb/IIIa. Similarly, initial binding to GPIIb/IIIa leads to a conformational change in fibrinogen that unmasks additional binding sites. Divalent fibrinogen and multivalent vWF molecules serve as bridges and bind adjacent platelets together. Once bound to GPIIb/IIIa, fibrinogen and vWF induce outside–inside signals that augment platelet activation and result in the activation of additional GPIIb/IIIa receptors, creating a positive feedback loop. Because GPIIb/IIIa acts as the final effector in platelet aggregation, it is a logical target for potent antiplatelet drugs (see Chapters 124 and 143). Fibrin, the ultimate product of the coagulation system, tethers the platelet aggregates together and anchors them to the site of injury.

Coagulation

Coagulation results in the generation of thrombin, which converts soluble fibrinogen to fibrin. Coagulation occurs through a series of concerted activation steps, wherein a nascent protease activates an inactive enzyme precursor (zymogen); a process that is repeated in a cascade-like fashion. The principal enzyme complexes are composed of a vitamin K–dependent enzyme and a non-enzyme cofactor assembled on anionic phospholipid membranes in a calcium-dependent fashion (see Chapter 125). Because each enzyme complex activates a substrate that becomes the enzyme component of the subsequent complex, a small stimulus can produce a robust response. Initially the small amount of thrombin generated activates non-enzyme cofactors and platelets. The activated platelets then provide an anionic surface on which the coagulation complexes assemble to promote rapid thrombin generation. Provision of an anionic phospholipid surface by activated platelets or other cells is essential to maximize the catalytic activity of these enzymatic complexes. The surface brings enzyme, cofactor, and substrate into proximity, thereby reducing the diffusional limitations of assembling soluble factors. The vitamin K-dependent factors, prothrombin and factors VII, IX, and X, are synthesized with post-translationally modified gamma-carboxy glutamic acid (Gla) residues at their amino termini that bear a greater negative charge. These Gla domains endow the factors with enhanced affinity for phosphatidylserine-rich membranes in a Ca^{2+}-dependent manner. Other proteins, the essential cofactors V and VIII, also have lipid-binding domains that promote their assembly into the activation complexes. The three predominant enzyme complexes involved in thrombin generation are extrinsic tenase, intrinsic tenase, and prothrombinase, named for their substrates, factor X and prothrombin (Fig. 121.4).

Coagulation can be divided into three phases: initiation, propagation, and termination.[19] These phases reflect the exquisite control over thrombin activity necessary to effect hemostasis. The initiation phase, which is predominantly mediated by extrinsic tenase, is responsible for generating the initial burst of thrombin required for platelet and coagulation factor activation. The propagation phase is largely mediated by intrinsic tenase and is responsible for the explosive thrombin generation necessary to sustain the coagulant response. The termination phase, which is mediated by numerous protease inhibitors, ensures that thrombin generation is localized and finite. Each of the activation complexes exhibits similar composition, assembly, and regulation.

Because initiation and propagation reactions require a membrane surface for assembly of factors, cells play a key role in coagulation. Tissue factor exposure on monocytes and extravascular cells and platelet membrane capacitation are recognized key steps. However, other cells also make important contributions. For example, damaged

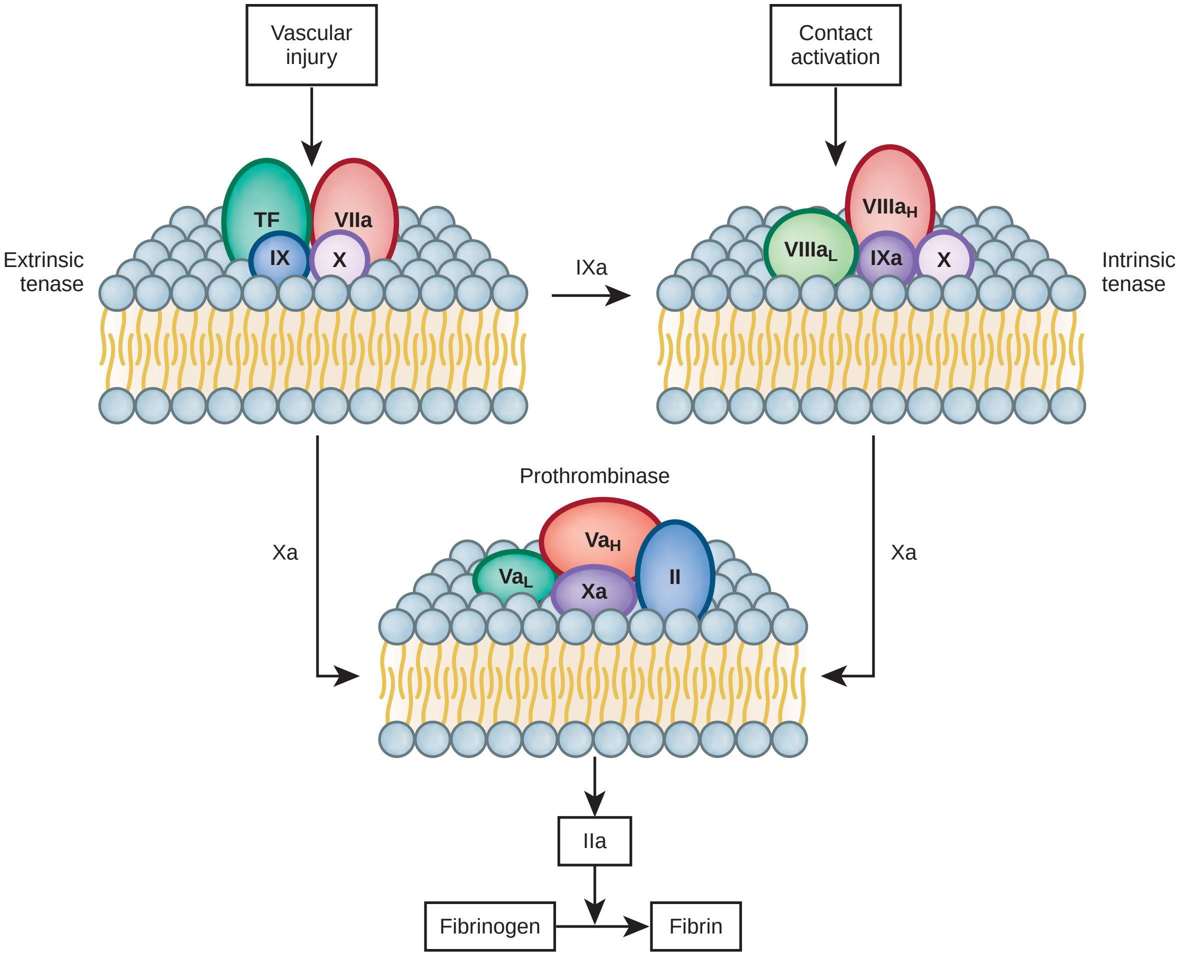

Figure 121.4 COAGULATION SYSTEM. Coagulation occurs through the action of discrete enzyme complexes, which are composed of a vitamin K–dependent enzyme and a non-enzyme cofactor. These complexes assemble on anionic phospholipid membranes in a calcium-dependent fashion. Vascular injury exposes tissue factor *(TF)*, which binds factor VIIa to form extrinsic tenase. Extrinsic tenase activates factors IX and X. Factor IXa binds to factor VIIIa to form intrinsic tenase, which activates factor X. The contact system also leads to activation of factor IX in response to exposure of anionic surfaces. Factor Xa binds to factor Va to form prothrombinase, which converts prothrombin (II) to thrombin (IIa). Thrombin then converts soluble fibrinogen into insoluble fibrin.

endothelium appears to support coagulation because mice deficient in PAR4, the major thrombin receptor on mouse platelets, still exhibit significant thrombus formation after laser injury. Red blood cells also bind to damaged endothelium and express procoagulant phospholipids on their surface, thereby providing additional sites for assembly of coagulation complexes. In addition, activated neutrophils extrude web-like structures known as neutrophil extracellular traps (NETs). Composed of nuclear DNA, histones, and metalloproteases, NETs promote coagulation by binding and activating platelets, trapping red blood cells, and activating the contact pathway. Thus, cells contribute to coagulation at numerous sites in the cascade.

Extrinsic Tenase

This complex forms upon exposure of tissue factor–expressing cells to the blood.[19] Tissue factor exposure occurs after atherosclerotic plaque rupture because the core of the plaque is rich in macrophages and other cells that express tissue factor. Denuding injury to the vessel wall also exposes tissue factor constitutively expressed by subendothelial fibroblasts and smooth muscle cells. In addition to cells in the vessel wall, activated circulating monocytes and monocyte-derived microparticles and extracellular vesicles (small membrane fragments) also provide a source of tissue factor. When tissue factor–bearing monocytes or microparticles bind to platelets or other leukocytes and their plasma membranes fuse, tissue factor transfer occurs. By binding to adhesion molecules expressed on activated endothelial cells or to P-selectin on activated platelets, these tissue factor–bearing cells, or microparticles, can initiate or augment coagulation. This phenomenon likely explains how venous thrombi develop in the absence of obvious vessel wall injury.

Tissue factor is an integral membrane protein that serves as a receptor for factor VIIa. Blood contains trace amounts of factor VIIa, which has negligible activity in the absence of tissue factor.[19] Although tissue factor is present on cell surfaces, it is proposed to exist in an encrypted, inactive form. The decryption step is thought to occur by a disulfide bond rearrangement catalyzed by protein-disulfide isomerase, and exposure of phosphatidylserine on the outer membrane surface. Factor VIIa binds tissue factor in a calcium-dependent fashion to form the extrinsic tenase complex, which is a potent activator of factors IX and X. Once activated, factor IXa and Xa serve as the enzyme components of intrinsic tenase and prothrombinase, respectively. Because sufficient levels of factor Xa and thrombin are formed in response to exposure of tissue factor, the extrinsic tenase complex is considered the essential mediator of the initiation phase.

Intrinsic Tenase

Factor IXa binds to factor VIIIa on anionic platelet or cell surfaces to form the intrinsic tenase complex.[20] Factor VIII circulates in blood in complex with vWF. Thrombin cleaves factor VIII, which converts it to its active form (factor VIIIa) and releases it from vWF. Activated platelets express binding sites for factor VIIIa. Once bound, factor

VIIIa binds factor IXa in a calcium-dependent fashion to form the intrinsic tenase complex, which then activates factor X. The loss in catalytic efficiency of intrinsic tenase that occurs with a deficiency of factors VIII or IX in hemophilia A and B, respectively, highlights their importance. Absence of the membrane or factor VIIIa almost completely abolishes enzymatic activity, and the catalytic efficiency of the complete complex is 10^6-fold greater than that of factor IXa alone. Because intrinsic tenase activates factor X at a rate 50- to 100-fold faster than extrinsic tenase, it plays a critical role in the amplification of factor Xa and subsequent thrombin generation.[21] Thus intrinsic tenase is crucial to the propagation phase of coagulation.

Contact Pathway

The contact pathway is so named because initial identification of its constituents (factors XII, XI, IX, and kallikrein) required contact with artificial agents such as ellagic acid or silica for activation. Such agents are used to trigger clotting when performing the activated partial thromboplastin time, a key global coagulation assay. Because of the reliance on artificial activators, the contact pathway lost prominence when the physiologic tissue factor pathway was identified. For many years, tissue factor exposure was regarded as the sole pathway for activation of coagulation and the contact system was thought to be unimportant for hemostasis because patients deficient in factor XII, prekallikrein, and high-molecular-weight kininogen do not have bleeding problems (see Chapters 125 and 135). Although patients with severe deficiency of factor XI can bleed after trauma or surgery, spontaneous bleeding is uncommon, and the plasma level of factor XI does not reliably predict the propensity for bleeding (see Chapter 135). The capacity of thrombin to feedback and activate factor XI may help to explain this phenomenon, thus re-igniting interest in factor XI because it bypasses the need for involvement of factor XII and the contact pathway. It also is possible that platelet-derived factor XI may be more important for hemostasis than circulating factor XI.[22]

There is increasing evidence that the contact pathway is important in thrombosis. Thus, catheters and other blood-contacting medical devices, such as stents, mechanical heart valves, and extracorporeal circuits trigger clotting through this mechanism. Factor XII, when bound to negatively charged or artificial surfaces, undergoes a conformational change that results in its activation. Factor XIIa converts prekallikrein to kallikrein in a reaction accelerated by high-molecular-weight kininogen, and factor XIIa and kallikrein both feedback to activate additional factor XII. Factor XIIa propagates coagulation by activating factor XI and generating factor XIa, the predominant activator of factor IX (Fig. 121.5).

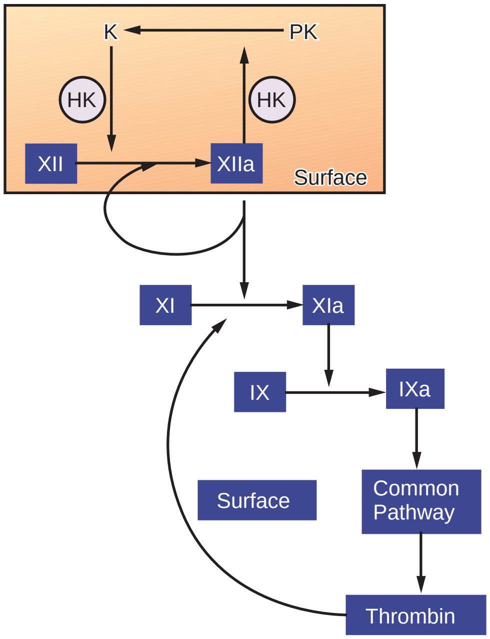

Figure 121.5 CONTACT SYSTEM. Factor XII (XII) is activated by contact with negatively charged surfaces. XIIa converts prekallikrein *(PK)* to kallikrein *(K)*, which can feed back to activate more XII. Likewise, XIIa also can feed back to amplify its own generation. About 75% of circulating PK is bound to high-molecular-weight kininogen *(HK)*, which localizes it to anionic surfaces and promotes PK activation. XIIa propagates clotting by activating XI, which then activates IX. The resultant IXa assembles into the intrinsic tenase complex, which activates X to initiate the common pathway of coagulation. Thrombin can feedback activate factor XI to further propagate coagulation.

This renewed interest in factor XI provided the stimulus to investigate the roles of factors XI and XII in thrombosis. Factor XI-deficient mice are protected from arterial injury–induced thrombosis to the same extent as factor IX-deficient mice, but do not experience bleeding, providing evidence of a clear demarcation between hemostasis and thrombosis. Mice lacking factor XII are also resistant to clot formation at sites of vascular injury. However, the physiologic mechanism for activation of the pathway remained unclear until studies showed that nuclear material released from neutrophils in the form of NETs, nucleic acids, and inorganic polyphosphates released from activated platelets or microorganisms activate coagulation in a contact pathway–dependent fashion.

Renewed interest in the contact pathway has spurred investigation of factors XI and XII as targets for new antithrombotic drugs. Agents targeting factors XI and XII include biological inhibitors, antisense oligonucleotides (ASO), antibodies, small molecule inhibitors, and aptamers. Both an ASO that reduces factor XI levels and an inhibitory antibody against factor Xa have been shown to reduce postoperative venous thrombosis in patients undergoing total knee arthroplasty, without an increase in bleeding. Similar interest in targeting the contact pathway is directed at device-related thrombosis. Thrombosis is a major cause of failure of blood-contacting medical devices, a problem that can lead to life-threatening complications including pulmonary embolism, coronary occlusion, and stroke, and activation of the contact pathway by the artificial surface is thought to be the primary cause. Therefore, the contact pathway has emerged as an attractive target for development of agents that reduce thrombosis with little impact on hemostasis.

The contact pathway may also contribute to the stability of arterial and venous thrombi.[23] NETs, and DNA and RNA released from damaged cells in atherosclerotic plaques, activate factor XII, and mice given DNA- or RNA-degrading enzymes exhibit attenuated thrombosis at sites of arterial injury. Polyphosphates released from activated platelets also activate factor XII, and may provide another stimulus for contact pathway activation. Mice deficient in factors XII or XI form small unstable thrombi at sites of arterial or venous damage, suggesting that factors XII and XI contribute to thrombogenesis (see Chapter 135). There is mounting evidence that the same is true in humans. Thus, patients with unstable angina have increased plasma levels of factor XIa that could reflect activation by factor XIIa, although activation by thrombin remains a possibility. The best evidence for the importance of the contact system comes from the results of phase 2 studies demonstrating that knock down of factor XI with an ASO or inhibition of factor XIa with a monoclonal antibody reduces the risk of postoperative venous thromboembolism in patients undergoing elective knee arthroplasty.[24,25] Therefore, the contact system is not only an important driver of thrombosis in blood-contacting medical devices, but may also contribute to thrombus propagation in situations where tissue factor initiates coagulation, such as after major surgery.

Prothrombinase

Being the only physiologic producer of thrombin, the prothrombinase complex is essential for hemostasis. Factor Xa binds to factor Va, its activated cofactor, on anionic phospholipid membrane surfaces in a calcium-dependent manner to form the prothrombinase complex. Activated platelets release factor V from their α-granules, and this platelet-derived factor V may play a more important role in hemostasis than its plasma counterpart.[26] Whereas plasma factor V requires thrombin activation to exert its cofactor activity, the partially activated factor V released from platelets already exhibits substantial cofactor activity. Activated platelets express specific factor Va binding sites on their surface, and bound factor Va serves as a receptor for factor Xa. The catalytic efficiency of factor Xa activation of prothrombin increases by 10^5-fold when factor Xa incorporates into the prothrombinase complex.[27] Prothrombin binds to the prothrombinase complex, where it undergoes conversion to thrombin in a reaction that releases prothrombin fragment 1.2 (F1.2). Plasma levels of F1.2, therefore, provide a marker of prothrombin activation. Prothrombin is the most abundant coagulation factor, and the efficiency of activation generates high local levels of thrombin.

Termination

Because thrombin clots fibrinogen, activates cells and platelets, and mediates anticoagulant and antifibrinolytic processes, it is imperative to regulate its activity and location. Thus, the termination phase plays a critical role in balancing the procoagulant forces. Two principal protease inhibitors modulate coagulation: TFPI and antithrombin. TFPI, which is located on platelets and microvascular endothelial cells, inhibits factor VIIa in a factor Xa-dependent manner. Because it binds TFPI, protein S serves both as a cofactor for this reaction and as a cofactor for APC -mediated inactivation of factors Va and VIIIa.[28] Adding to its anticoagulant role, TFPI also binds factor V and attenuates its assembly into the prothrombinase complex.[28] TFPI effectively halts tissue factor-mediated initiation of coagulation, but not before sufficient factor Xa is generated to initiate clotting.

The high levels of thrombin produced during the amplification phase are controlled by antithrombin. This serine protease inhibitor (serpin) also inactivates other coagulation proteases, including factors VIIa, IXa, Xa, and XIa. Although antithrombin is abundant, it exhibits only moderate inhibitory activity, except in the presence of cell-associated glycosaminoglycans, such as heparan sulfate. This is the biochemical basis for use of heparin, a structurally similar glycosaminoglycan derived from mast and intestinal mucosa cells that is used as an anticoagulant (see Chapter 143).

The protein C anticoagulant pathway that is catalyzed by thrombin mediates further regulation of thrombin generation. In the presence of endothelial surface bound thrombomodulin and EPCR, thrombin catalyzes the activation of protein C. APC is an important anticoagulant and anti-inflammatory mediator. In the context of hemostasis, APC inactivates FVa and FVIIIa to forms unable to act as cofactors in their respective activation complexes. Inactivation of FVIIIa by APC is promoted by intact FV and its activation intermediates, but not by FVa.[28]

The regulatory processes mediated by TFPI, antithrombin and APC ensure that thrombin generation is localized and limited. However, under conditions of hemostatic imbalance, sufficient thrombin is produced to overcome these checks and balances to ensure that coagulation occurs.

Fibrin Formation

Thrombin converts soluble fibrinogen into insoluble fibrin. Fibrinogen is a dimeric molecule, each half of which is composed of three polypeptide chains, the Aα, Bβ, and γ chains. Numerous disulfide bonds covalently link the chains together and join the two halves of the fibrinogen molecule (Fig. 121.6). Electron micrographic studies of fibrinogen reveal a trinodular structure with a central E domain flanked by two D domains. Crystal structures show symmetry of design with the central E domain, which contains the amino termini of the fibrinogen chains, joined to the lateral D domains by coiled-coil regions.

Fibrinogen circulates in a soluble form. Thrombin binds to the amino termini of the Aα and Bβ chains of fibrinogen, where it cleaves specific peptide bonds to release fibrinopeptide A and fibrinopeptide B and generates fibrin monomer (see Fig. 121.6). Because they are products of thrombin action on fibrinogen, plasma levels of these fibrinopeptides provide an index of thrombin activity. Fibrinopeptide release creates new amino termini that extend as knobs from the E domain of one fibrin monomer and insert into preformed holes in the D domains of other fibrin monomers. This creates long strands known as protofibrils, consisting of fibrin monomers noncovalently linked together in a half-staggered, overlapping fashion.[29]

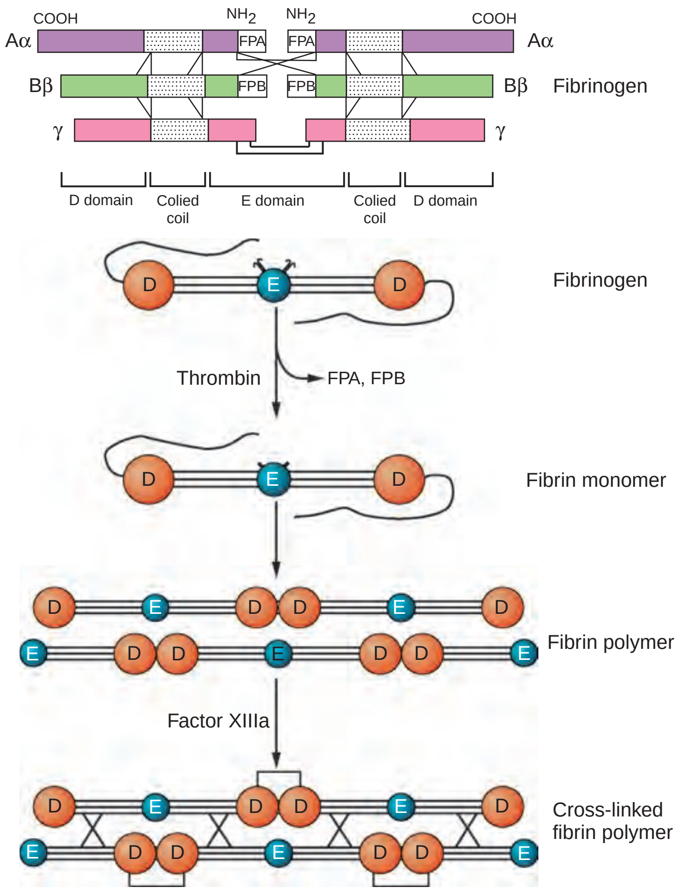

Figure 121.6 FIBRINOGEN STRUCTURE AND CONVERSION OF FIBRINOGEN TO FIBRIN. A dimeric molecule, each half of fibrinogen is composed of three polypeptide chains, Aα, Bβ, and γ. Numerous disulfide bonds (lines) covalently link the chains together and join the two halves of the fibrinogen molecule to yield a trinodular structure with a central E domain linked via the coiled-coil regions to two lateral D domains. To convert fibrinogen to fibrin, thrombin cleaves specific peptide bonds at the amino *(NH2)* termini of the Aα and Bβ chains of fibrinogen to release fibrinopeptide A *(FPA)* and fibrinopeptide B *(FPB)*, thereby generating fibrin monomer. Fibrin monomers polymerize to generate protofibrils arranged in a half-staggered overlapping fashion. By covalently cross-linking α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin network and renders it resistant to degradation.

Noncovalently linked fibrin protofibrils lack tensile strength. The stability of the fibrin network is enhanced by platelets and procoagulant cells.[29] Platelets not only bind fibrin via GPIIb/IIIa and promote formation of a dense fibrin network, but they also release factor XIII. By covalently cross-linking α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin in a calcium-dependent fashion and renders it relatively resistant to physical strain and degradation. A form of Factor XIII also circulates in blood as a heterodimer consisting of pairs of A and B subunits. The active and calcium binding sites on factor XIII are localized to the A subunit. Platelets contain large amounts of factor XIII in their cytoplasm, but platelet-derived factor XIII consists only of the A subunits (see Chapter 124). Both plasma and platelet factor XIII are activated by thrombin in a fibrin-dependent manner. Crosslinking of fibrin contributes to its tensile strength and traps erythrocytes, thereby contributing to the integrity of the thrombus.

Hemostasis depends on the dynamic balance between the formation of fibrin and its degradation. The fibrinolytic system mediates fibrin breakdown.

Fibrinolytic System

Fibrinolysis initiates when plasminogen activators convert plasminogen to plasmin, which then degrades fibrin into soluble fragments. Blood contains two immunologically and functionally distinct plasminogen activators, t-PA and u-PA. t-PA mediates intravascular fibrin degradation, whereas u-PA binds to a specific u-PA receptor (u-PAR) on the surface of cells, where it activates cell-bound plasminogen. Consequently, pericellular proteolysis during cell migration, and tissue remodeling and repair are the major functions of u-PA.[30]

Regulation of fibrinolysis occurs at several levels (see Chapter 125). The substrate of the fibrinolytic system, fibrin, serves a transient but essential stimulatory role that subsides as it degrades. The serpins, PAI-1, and to a lesser extent, PAI-2, inhibit the plasminogen activators, whereas α2-antiplasmin inhibits plasmin. Endothelial cells synthesize PAI-1, which inhibits both t-PA and u-PA, whereas monocytes and the placenta synthesize PAI-2, which specifically inhibits u-PA. Thrombin-activatable fibrinolysis inhibitor (TAFI) also modulates fibrinolysis and provides a link between fibrinolysis and coagulation.[30] Thrombosis can occur if there is impaired activation of the fibrinolytic system, whereas excessive activation leads to bleeding. Therefore, a review of the mechanisms of action of t-PA, u-PA, and TAFI is worthwhile.

Mechanism of Action of Tissue-Type Plasminogen Activator

t-PA, a serine protease, contains five discrete domains: a fibronectin-like finger domain, an epidermal growth factor (EGF) domain, two kringle domains, and a protease domain. Synthesized as a single-chain polypeptide, t-PA is converted into a two-chain form by plasmin. Single- and two-chain forms of t-PA convert plasminogen to plasmin. Native Glu-plasminogen is a single-chain polypeptide with a Glu residue at its amino-terminus. Plasmin cleavage near the amino-terminus generates Lys-plasminogen, a truncated form with a Lys residue at its new amino terminus.[31] t-PA cleaves a single peptide bond to convert single-chain Glu- or Lys-plasminogen into two-chain plasmin, composed of a heavy chain containing five kringle domains and a light chain containing the catalytic domain. Because its open conformation exposes the t-PA cleavage site, Lys-plasminogen is a better substrate than Glu-plasminogen, which assumes a circular closed conformation that renders this bond less accessible.

t-PA has little enzymatic activity in the absence of fibrin, but its activity increases by at least three orders of magnitude when fibrin is present. This increase in activity reflects the capacity of fibrin to serve as a template that binds t-PA and plasminogen and promotes their interaction. t-PA binds to fibrin via its finger and second kringle domains, whereas plasminogen binds fibrin via its kringle domains. Kringle domains are triple loop-like structures that bind Lys residues on fibrin and other proteins. As fibrin undergoes degradation, more Lys residues are exposed, which provide additional binding sites for t-PA and plasminogen. Consequently, degraded fibrin stimulates t-PA activation of plasminogen more than intact fibrin.

α2-Antiplasmin, another serpin, rapidly inhibits circulating plasmin by docking to its first kringle domain and then inhibiting the active site.[30] Because plasmin also binds to fibrin via its kringle domains, plasmin generated on the fibrin surface resists inhibition by α2-antiplasmin. This phenomenon endows fibrin-bound plasmin with the capacity to degrade fibrin. Factor XIIIa cross-links small amounts of α2-antiplasmin onto fibrin, which prevents premature fibrinolysis.[29]

Like fibrin, endothelial cells bind t-PA and plasminogen and markedly promote activation by colocalization of enzyme and substrate. Cell-surface binding is mediated by receptors such as annexin II, gangliosides, and α-enolase, as well as an orphan transmembrane protein expressed with a carboxy-terminal lysine residue. Plasminogen binds to exposed lysine residues on these receptors via its kringle domains. Lipoprotein(a) [LP(a)], which also possesses kringle domains, impairs cell-based fibrinolysis by competing with plasminogen for cell-surface binding. This phenomenon may explain the association between elevated LP(a) levels and atherosclerosis.

Mechanism of Action of Urokinase-Type Plasminogen Activator

Synthesized as a single-chain polypeptide, single-chain u-PA (scu-PA) has minimal enzymatic activity. Plasmin converts scu-PA into a two-chain form that is enzymatically active and capable of binding u-PAR, the u-PA receptor on cell surfaces. Further cleavage at the amino-terminus of two-chain u-PA yields a truncated, lower-molecular-weight form that lacks the u-PAR binding domain.

Two-chain forms of u-PA readily convert plasminogen to plasmin in the absence or presence of fibrin.[31] In contrast, scu-PA does not activate plasminogen in the absence of fibrin, but it can activate fibrin-bound plasminogen, because plasminogen adopts the readily activatable open conformation. Like the higher-molecular-weight form of two-chain u-PA, scu-PA binds to cell surface u-PAR, where plasmin can activate it. Many tumor cells elaborate u-PA and express u-PAR on their surface. As with fibrin and plasminogen receptors, colocalization of the reactants greatly promotes activation. Plasmin generated on these cancer cells endows them with the capacity for metastasis because plasmin readily degrades components of the extracellular matrix and activates growth factors and other degradative proteases.

Mechanism of Action of Thrombin-Activatable Fibrinolysis Inhibitor

TAFI, a procarboxypeptidase B–like molecule synthesized in the liver, circulates in blood in a latent form where thrombin bound to thrombomodulin can activate it to TAFIa (see Chapter 125). Unless bound to thrombomodulin, thrombin activates TAFI inefficiently.[32] TAFIa attenuates fibrinolysis by cleaving Lys residues from the carboxy termini of chains of degrading fibrin, thereby removing essential binding sites for plasminogen, plasmin, and t-PA, attenuating activation, and promoting plasmin inhibition. TAFI links fibrinolysis to coagulation because the thrombin–thrombomodulin complex not only activates TAFI, which attenuates fibrinolysis, but also activates protein C, which mutes thrombin generation.

TAFIa has a short half-life in plasma because the enzyme is unstable. Genetic polymorphisms can result in synthesis of more stable forms of TAFIa. Persistent attenuation of fibrinolysis by these variant forms of TAFIa may render patients susceptible to thrombosis.

DISORDERS OF HEMOSTASIS OR THROMBOSIS

A physiologic host defense mechanism, hemostasis focuses on arrest of bleeding by forming hemostatic plugs composed of platelets and fibrin at sites of vessel injury. In contrast, thrombosis reflects a pathologic process associated with intravascular thrombi that occlude the lumens of arteries or veins. Disorders are typically caused by disruption of one of the three axes of Virchow's triad: the vasculature, blood flow, or hypercoagulability of the blood. These processes are interdependent and integrated, and their dysregulation leads to immunothrombosis (see box on Immunohemostasis).

Hemostatic Disorders

Bleeding can occur if there is abnormal platelet plug formation and/or reduced thrombin generation and subsequent fibrin clot formation at the site of vascular injury, disorders of primary and secondary hemostasis, respectively. Bleeding also can occur if the platelet/fibrin clot is prematurely degraded because of excessive fibrinolysis; a disorder of tertiary hemostasis. The features distinguishing disorders of primary, secondary, and tertiary hemostasis are outlined in Table 121.1. Hemorrhagic disorders can be inherited or acquired, and the clinical and laboratory evaluation of such disorders is detailed in Chapters 126 and 127, respectively.

Disorders of Primary Hemostasis

Platelet plug formation, the first step in the arrest of bleeding at sites of injury, requires three key components: (a) an adequate number of functional platelets, (b) vWF, the molecular glue that mediates platelet adhesion to the damaged vessel wall even in the face of high shear, and (c) a normal blood vessel that constricts in response to injury (Table 121.2). Because the platelet plug provides the first line of defense against bleeding, patients with disorders of primary hemostasis often present with immediate bleeding after injury, and petechiae (pinpoint hemorrhages) may be noted. In addition to skin bleeding, mucocutaneous bleeding, which may manifest as epistaxis, bleeding gums, or hematochezia, is common as is excessive menstrual bleeding in women (see Chapter 126).

Disorders of primary hemostasis may be inherited or acquired.[33] Thrombocytopenia, or congenital or acquired disorders of platelet function, are common causes of bleeding. Thrombocytopenia can be the result of decreased production, which can occur because of failure, infiltration, or fibrosis of the bone marrow (see Chapters 30 and 31), increased platelet destruction, or abnormal distribution because of platelet pooling in the spleen (see Chapter 130). Increased destruction of platelets can occur via immune mechanisms, such as immune thrombocytopenic purpura (ITP), alloimmune thrombocytopenia, posttransfusion purpura, and drug-induced thrombocytopenia including heparin-induced thrombocytopenia (see Chapters 129, 130 and 131), or nonimmune mechanisms, which include microangiopathic disorders, such as thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (see Chapter 132), as well as consumption because of activation of coagulation, such as occurs with disseminated intravascular coagulation (see Chapter 137).

TABLE 121.1 **Comparison of the Features of Disorders of Primary, Secondary, or Tertiary Hemostasis**

Features	Primary	Secondary	Tertiary
Components involved	Platelets, vWF, and vessel wall	Coagulation	Fibrinolysis factors
Site of bleeding	Skin and mucocutaneous and soft tissues	Muscles, joints, and deep tissues	Wounds and genitourinary tract
Physical findings	Petechiae and ecchymoses	Hematomas and hemarthroses	Hematuria and menorrhagia
Timing of bleeding	Immediate	Delayed	Delayed
Inheritance	Autosomal dominant	Autosomal or X-linked recessive	Autosomal recessive

vWF, von Willebrand factor.

TABLE 121.2 **Disorders of Primary Hemostasis**

Components Affected	Causes
Platelets	Quantitative or qualitative platelet disorders
vWF	Inherited or acquired deficiency or dysfunction of vWF

vWF, von Willebrand factor.

Platelet function disorders include disorders of platelet (a) adhesion, such as von Willebrand disease (see Chapter 133) and Bernard-Soulier syndrome (see Chapter 124); (b) thromboxane synthesis; (c) secretion, such as alpha or dense granule deficiency, or aspirin-like secretion defects; (d) aggregation, such as Glanzmann thrombasthenia (see Chapter 124); or (e) procoagulant activity (Scott syndrome) where the platelets fail to support clotting factor complex assembly (see Chapter 124). Acquired disorders of platelet function can occur in patients taking drugs that impair platelet function, such as aspirin or nonsteroidal anti-inflammatory drugs, or in patients with uremia, paraproteins, myelodysplastic, or myeloproliferative disorders (see Chapter 128).

Bleeding can also occur with inflammation or malformations of the blood vessels, or abnormalities of the connective tissue supporting the blood vessels. Inflammatory disorders include Henoch-Schonlein purpura (see Chapter 148) and the vasculitis that occurs with paraproteins or cryoglobulins, or in patients with systemic lupus erythematosus or other immune disorders.[34] Hereditary hemorrhagic telangiectasia is an inherited disorder associated with malformations of the capillaries. Telangiectatic vessels can often be seen in the oral and nasal cavities of patients with this disorder and bleeding episodes, primarily from the nose and gastrointestinal tract, are common. Abnormalities of the connective tissue matrix supporting the blood vessels include Marfan syndrome, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum.[35] Patients with these disorders frequently report easy bruising.

Disorders of Secondary Hemostasis

Secondary hemostasis depends on rapid generation of sufficient amounts of thrombin to generate a fibrin mesh that not only consolidates the platelet aggregates that form at sites of vascular injury, but also is stable enough to provide a barrier that prevents leakage of blood from the damaged blood vessel.[29] Secondary hemostasis can be compromised by (a) impaired thrombin generation because of congenital or acquired deficiencies of coagulation factors or cofactors or intake of drugs that inhibit one or more steps in the coagulation pathways, (b) congenital or acquired fibrinogen deficiency or dysfunction, and/or (c) impaired cross-linking of fibrinogen because of congenital or acquired deficiency of factor XIII (Table 121.3).

Examples of inherited deficiencies of coagulation factors include hemophilia A and B, deficiencies of factor VIII and factor IX, respectively (see Chapter 134). Because of redundancy in the coagulation system, only patients with a factor VIII or factor IX level less than 1% have severe disease characterized by spontaneous bleeding or bleeding

TABLE 121.3 **Disorders of Secondary Hemostasis**

Components Affected	Causes
Coagulation factors	Congenital deficiency, autoantibodies, increased consumption, or drugs that attenuate thrombin generation or thrombin activity.
Fibrinogen	Decreased production, increased consumption or synthesis of an abnormal protein. Impaired fibrin polymerization because of fibrin(ogen) degradation products or paraproteins.
Fibrin cross-linking	Congenital or acquired factor XIII deficiency

with minimal trauma. Those with factor levels between 1% and 5% have an intermediate phenotype, whereas patients with factor VIII or IX levels above 5% usually have mild disease and bleed only with trauma or surgery. The frequency of bleeding episodes in patients with severe hemophilia can be reduced with prophylactic administration of the appropriate factor concentrate; such treatment is also administered to hemophiliacs with overt bleeding, or in preparation for surgery or other major interventions. Long-lasting factor VIII and IX molecules have been developed to reduce the frequency of factor replacement. The half-lives of these recombinant full-length or truncated proteins have been prolonged by conjugating them to hydrophilic polymers such as polyethylene glycol, or by fusing them with albumin or the Fc fragment of IgG1. Conjugation to polyethylene glycol protects the proteins from proteolytic degradation, whereas fusion technology creates new recycling pathways that diminish natural protein breakdown (see Chapter 134). Management of hemophilia becomes more complicated if patients develop inhibitory antibodies that attenuate or abolish the activity of the infused factor. Emicizumab, the first synthetic clotting factor, is a bispecific antibody that bypasses factor VIII by binding to factor IXa and bridging it to factor X. Emicizumab is now used for treatment of hemophilia A in patients with or without inhibitors (see Chapter 134).

Congenital deficiencies of prothrombin (factor II), factors V, VII, X, or XI (hemophilia C), or fibrinogen are less common causes of bleeding (see Chapter 135). In contrast, deficiencies of components of the contact pathway—factor XII, high-molecular-weight kininogen, and prekallikrein—are not associated with bleeding. The clinical and laboratory evaluation of such patients is detailed in Chapters 126 and 127, respectively, whereas their treatment is outlined in Chapters 115 and 135.

Acquired deficiencies of coagulation factors can result from decreased synthesis due to severe liver disease, vitamin K deficiency or intake of drugs that interfere with vitamin K metabolism, consumption because of excessive activation of coagulation (e.g., disseminated intravascular coagulation; see Chapter 137), or accelerated clearance due to adsorption by paraproteins or amyloid (see Chapters 91 and 92), or to autoantibodies that shorten the half-life, attenuate, or abolish clotting factor activity.

Congenital disorders of fibrinogen include absence or low levels of fibrinogen (afibrinogenemia and hypofibrinogenemia, respectively), or synthesis of a dysfunctional protein (dysfibrinogenemia). Acquired disorders of fibrinogen include decreased synthesis or production of an abnormal fibrinogen, increased fibrinogen consumption or the presence of inhibitors that interfere with fibrin polymerization, such as paraproteins, autoantibodies, particularly in patients with systemic lupus erythematosus or other immune disorders or elevated levels of fibrin(ogen) degradation products.

Stabilization of fibrin requires cross-linking of the α and γ chains of adjacent fibrin monomers to yield a polymer that is resistant to premature breakdown. Factor XIIIa performs this function by catalyzing the condensation of lysine residues on one chain with glutamic acid residues on another chain.[29] Congenital or acquired deficiency of factor XIII can impair cross-linking, resulting in bleeding. The hallmarks of severe factor XIII deficiency include umbilical stump bleeding in the neonatal period (see Chapters 135 and 148), intracranial hemorrhage with little or no trauma, recurrent soft tissue hemorrhages, and, in females, recurrent spontaneous miscarriages.

Disorders of Tertiary Hemostasis

Tertiary hemostasis depends on the generation of plasmin, which degrades fibrin and restores blood flow in damaged vessels. Premature lysis of fibrin in hemostatic plugs can lead to bleeding; this can occur systemically or can be localized (Table 121.4). Systemic fibrinolysis that occurs in the absence of activation of coagulation, the so-called primary hyperfibrinolysis, is rare but can occur with inherited deficiency of PAI-1 or α2-antiplasmin, the inhibitors of the plasminogen activators and plasmin, respectively, advanced liver disease, and some snakebites. More commonly, systemic hyperfibrinolysis is secondary to activation of coagulation by procoagulants such as tissue factor (e.g., in patients with metastatic cancer) or artificial surfaces (e.g., in cardiopulmonary bypass surgery or with cardiac assist devices). Examples of localized hyperfibrinolysis include menorrhagia or hematuria after prostatectomy triggered by excessive plasmin generation induced by the high concentrations of t-PA and u-PA in the uterus and genitourinary tract, respectively.

TABLE 121.4 Disorders of Tertiary Hemostasis

Component Affected	Causes
Plasminogen activators	Increased t-PA or u-PA release in the GU tract or other tissues.
Plasmin	Deficiency of PAI-1 or α2-antiplasmin, resulting in an increased plasmin concentration.

GU, Genitourinary; *PAI-1*, plasminogen activator inhibitor 1; *t-PA*, tissue plasminogen activator; *u-PA*, urokinase-type plasminogen activator.

Thrombotic Disorders

Thrombosis may occur in arteries, in the chambers of the heart, or in the veins. Factors contributing to thrombosis in these sites include endothelial injury or activation, reduced blood flow, and hypercoagulability of the blood, the so-called Virchow triad.

Arterial Thrombosis

Most arterial thrombi occur on top of disrupted atherosclerotic plaques. Plaques with a thin fibrous cap and a lipid-rich core are most prone to disruption. Erosion or rupture of the fibrous cap exposes thrombogenic material in the lipid-rich core to the blood, and triggers platelet activation and thrombin generation (see Chapter 142). The extent of plaque disruption and the content of thrombogenic material in the plaque determine the consequences of the event, regardless of whether it occurs in the cerebral circulation (see Chapter 144), the coronary circulation (see Chapter 145), or the major arteries of the legs (see Chapter 146), but host factors also contribute. Breakdown of regulatory mechanisms that limit platelet activation and inhibit coagulation can augment thrombosis at sites of plaque disruption.

Decreased production of nitric oxide and prostacyclin by diseased endothelial cells can trigger vasoconstriction and platelet activation. Proinflammatory cytokines lower thrombomodulin expression by endothelial cells, thereby sustaining thrombin generation, and stimulate PAI-1 expression, which inhibits fibrinolysis.

Products of blood coagulation contribute to atherogenesis, as well as its complications (see Chapter 142). Microscopic erosions in the vessel wall trigger the formation of tiny platelet-rich thrombi.[36] Activated platelets release PDGF and TGF-β, which promote a fibrotic response. Thrombin generated at the site of injury not only activates platelets and converts fibrinogen to fibrin, but also activates PAR-1 on smooth muscle cells and induces their proliferation, migration, and elaboration of extracellular matrix. Incorporation of thrombi into plaques promotes plaque growth, and decreased endothelial cell production of heparan sulfate that normally limits smooth muscle proliferation contributes to plaque expansion.[2] The multiple links between atherosclerosis and thrombosis have prompted the term atherothrombosis (see Chapter 142).

Intracardiac Thrombosis

Thrombi can form in the left ventricle after transmural myocardial infarction or with an aneurysm or dyskinetic ventricle, or in the left atrial appendage, particularly in patients with atrial fibrillation (see Chapter 147). Damage to the endothelium after myocardial infarction and abnormal blood flow are the major triggers for left ventricular thrombus formation. With rapid atrial fibrillation, there also is stasis and turbulent blood flow in the left atrial appendage, which is a long, blind-ended trabeculated pouch.[37] This may lead to localized activation of endothelial cells and subsequent loss of their anticoagulant phenotype, a process amplified by adhesion of leukocytes and subsequent elaboration of proinflammatory cytokines. The generation of thrombin creates a local hypercoagulable state that likely promotes thrombus formation on the abnormal endothelium. Embolization of these thrombi to the brain is a common cause of ischemic stroke and the major cause of mortality and morbidity in patients with atrial fibrillation.

Venous Thrombosis

The causes of venous thrombosis include those associated with hypercoagulability, which can be genetic or acquired, and the mainly acquired risk factors, such as advanced age, obesity, or cancer, which are associated with immobility (see Chapters 138 and 140). Inherited hypercoagulable states and these acquired risk factors combine to establish the intrinsic risk of thrombosis for each individual.[38] Superimposed triggering factors, such as surgery, pregnancy, or hormonal therapy, modify this risk, and thrombosis occurs when the combination of genetic, acquired, and triggering forces exceed a critical threshold.[39]

Some acquired or triggering factors entail a higher risk than others. For example, major orthopedic surgery, neurosurgery, multiple trauma, and metastatic cancer (particularly adenocarcinoma) are associated with the highest risk; prolonged bed rest, antiphospholipid antibodies (see Chapter 139), and the puerperium are associated with an intermediate risk; whereas pregnancy, obesity, long-distance travel, or the use of oral contraceptives or hormonal replacement therapy are mild risk factors. Up to half of the patients who present with venous thromboembolism before the age of 45 have inherited hypercoagulable disorders—so-called thrombophilia (see Chapter 138)—particularly those whose event occurred in the absence of risk factors or with minimal provocation, such as after minor trauma or a long-haul flight or with estrogen use.[39]

TREATMENT OF DISORDERS OF HEMOSTASIS AND THROMBOSIS

By the midpoint of the 20th century, two major anticoagulant drugs had been discovered, characterized, and given to humans for prevention or treatment of thrombotic disorders. Heparin and vitamin K antagonists, such as warfarin, dominated treatment regimens for decades. In the same era, determination of their mechanisms of action and dosing was aided by the discovery of the main players of the coagulation system, resulting from the development of sensitive functional assays to monitor their activity. Heparin and warfarin still represent effective members of the anticoagulant armamentarium; however, detailed understanding of the biochemistry and cell biology of hemostasis has directly contributed to the development of new therapies. Heparin derivatives with more predictable pharmacokinetics have improved therapy and reduced complications (see Chapter 143). Small molecule, direct inhibitors of thrombin and factor Xa have been developed. These direct oral anticoagulants include dabigatran, rivaroxaban, apixaban, and edoxaban; agents that are replacing conventional therapies (see Chapter 143). The resurgence of interest in the contact system as a potential mediator of thrombosis has led to the investigation of factors XI and XII as new targets for therapy.[40] On the hemostasis side, regimens to treat bleeding disorders include administration of factors VIIa, VIII, or IX, and prothrombin complex concentrate (see Chapters 134, 135 and 136). The new agents and treatment regimens highlight the therapeutic benefit that has resulted from our detailed understanding of hemostasis and thrombosis and provide optimism about further reducing cardiovascular disease as a leading cause of death.

CHAPTER 122

BLOOD VESSELS

Aly Karsan and Janusz Rak

HEMOSTATIC, HEMATOPOIETIC, AND VASCULAR SYSTEMS AS A FUNCTIONAL CONTINUUM

Diseases affecting the bone marrow (BM) and peripheral blood are closely intertwined with the state of the vascular system,[1] which acts as a niche, conduit, and regulator of blood cells.[2] This is exemplified by the anatomic proximity and interactions among several related cellular populations, including hematopoietic stem and progenitor cells and their mature progeny, endothelial cells, perivascular tissues, and other components involved in hematopoiesis as well as blood vessel formation, repair, homeostasis, and patency.[2,3] Recent progress in understanding the molecular mechanisms involved in communications among these cells increasingly informs clinical practice and drug discovery efforts.[2,4,5] For instance, agents designed to block vascular growth (antiangiogenics) in solid tumors also elicit hematologic perturbations,[6] and have been considered in the treatment of hematopoietic malignancies with enhanced BM vascularity.[7] Indeed, the hematopoietic, hemostatic, and vascular compartments can be viewed as a functional continuum, both in health and in disease.

STRUCTURE AND FUNCTION OF THE VESSEL WALL

The circulatory system has traditionally been divided into the macrovasculature (vessels >100 μm in diameter) and the microvasculature, each endowed with distinct functional roles. The arterial system transports blood to tissues, resists changes in blood pressure proximally, and regulates blood flow distally. Veins return blood to the heart and act as capacitance vessels because they contain, at any given time, approximately 70% of the total blood volume. Venules with luminal diameters less than 50 μm are structurally similar to capillaries.[8] Capillaries and microvessels in general are particularly important in the exchange of gases, macromolecules, and cells between blood and tissue. Although large vessels play an important role in maintaining vascular tone, a significant proportion of peripheral resistance arises from the capillaries.[8] Capillary endothelial cells also have a metabolic role, as in the conversion of angiotensin and hydrolysis of lipoproteins. Finally, the formation of new vessels is initiated in the microvasculature.

Macrovasculature

Large vessels are composed of three layers: intima, media, and adventitia.[8] The intima comprises the endothelium and the subendothelium. The endothelial cells of large vessels contain distinct rod-shaped secretory organelles, called Weibel-Palade bodies, which contain von Willebrand factor (vWF) and other proteins, such as P-selectin and angiopoietin-2, that contribute to inflammation, angiogenesis, and tissue repair.[9] The abluminal face of the endothelium rests on a basement membrane, which supports the endothelial cell and can act as a secondary barrier against the extravasation of blood.[10] The subendothelial matrix contains occasional smooth muscle cells and scattered macrophages. Both smooth muscle cells and endothelial cells contribute to the extracellular matrix (ECM) of the intima, along with ECM components such as elastin and collagen.[11,12] In large vessels, the media is separated from the intima by a layer of elastin, the internal elastic lamina. Diseases associated with mutations in elastin include supravalvular aortic stenosis, Williams syndrome, and autosomal dominant *cutis laxa*.[13]

The medial layer is composed primarily of concentric layers of smooth muscle cells and their secreted matrix, which is a complex mix of glycoproteins and proteoglycans. This layer is responsible for the structural integrity of the wall and for maintaining vascular tone. Mutations of the fibrillin-1 gene, a microfilament protein in elastic fibers, result in the disruption of the media in Marfan syndrome.[14] Defects of type III collagen can cause aortic rupture in patients with Ehlers-Danlos syndrome type IV.[11] An attenuated band of elastic fibers, the external elastic lamina, separates the adventitia from the media.

The adventitia is composed of loose connective tissue, and the outer portion of the media contains an ECM scaffold containing fibroblasts, small nerves, progenitor cells, lymphatic vessels, and nutritive blood vessels, the *vasa vasorum*. The adventitia has been recognized as a dynamic environment important in the growth, disease, and repair of the artery. The external limit of the adventitial layer is loosely defined and becomes contiguous with the surrounding connective tissue of the organ.[8]

Microvasculature

Capillaries and postcapillary venules are composed of two main cell types: endothelial cells and pericytes.[15] The two cell types interact to contribute to basement membrane formation, maintenance, and remodeling. Long pericyte processes extend over the abluminal surface of each endothelial cell,[15] and reciprocal extensions of the endothelial cell make contact with the pericyte. Pericytes and endothelial cells form specialized junctions with each other at distinct points in the basement membrane. These adherens junctions connect the cytoskeleton of pericytes and endothelial cells, mediating contact inhibition through contractile forces. Gap junctions between the cytoplasm of pericytes and endothelial cells enable communication through the passage of metabolites and ionic currents. Like endothelial cells, pericytes are also heterogeneous and display a variety of functions including[15]: (1) contractile activity, which regulates blood flow; (2) multipotential capabilities resulting in differentiation to adipocytes, osteoblasts, phagocytes, and smooth muscle cells; and (3) regulation of capillary growth. In animal models and human disease (e.g., diabetic microangiopathy, hemangiomata), a lack of pericytes is associated with microaneurysms and disordered microvasculature.[16]

ENDOTHELIAL STRUCTURE, FUNCTION, AND HETEROGENEITY

The endothelium exhibits polarity manifested by the asymmetric distribution of cell surface glycoproteins and by the unidirectional secretion of some ECM proteins and mediators.[17] In cultured endothelial cells, apical–basal polarity is established before confluence, but intercellular junctions may have a role in maintaining polarity and cell viability in vivo.[18,19]

Four types of intercellular junctions between adjacent endothelial cells have been described: tight junctions, gap junctions, adherens junctions, and desmosomes (see Chapter 15). Their distribution varies along the vascular tree, with tight junctions occurring more frequently in the larger arteries and brain vasculature, correlating with a more stringent requirement for permeability control. The molecular structure of endothelial tight junctions is similar to that of epithelial cells, consisting of a network of fibrils, with the integral membrane components comprising occludin, claudin-5, and junctional adhesion molecules (JAMs), which associate with various structural and signaling proteins on the cytoplasmic face.[18]

The distribution of gap junctions tends to follow that of tight junctions. Connexin 37, connexin 40, and connexin 43 are gap junction proteins that have been detected in endothelial cells. Gap junctions mediate communication between adjacent endothelial cells and between endothelial cells and pericytes or smooth muscle cells; they also contribute to the endothelial barrier and vascular integrity.

Adherens junctions are formed by transmembrane glycoproteins called cadherins, which make the link between cell-to-cell contacts and the cytoskeleton, and thus sense and respond to mechanical forces at the intercellular interface and regulate permeability. Several different types of cadherins are expressed in endothelial cells. The endothelial-specific cadherin vascular endothelial cadherin (VE-cadherin [Cadherin-5]) is expressed on virtually all types of endothelium.[20] Like other cadherins, VE-cadherin forms homotypic contacts with VE-cadherin on adjacent cells. Within the cell, VE-cadherin complexes with catenins, which, through other proteins, contact the actin cytoskeleton. Homotypic engagement of VE-cadherin across adjacent cells results in density-dependent inhibition of endothelial proliferation. This process is thought to be mediated by the association of vascular endothelial growth factor receptor 2 (VEGFR-2) with VE-cadherin, which sequesters VEGFR-2 at the membrane and prevents its internalization into signaling compartments.[20]

Other membrane proteins located at inter-endothelial junctions include platelet endothelial cell adhesion molecule 1 (PECAM-1), which may be important in directing the formation of junctions, as well as nectins, JAMs, endothelial cell-selective adhesion molecule (ESAM), and integrins (particularly $\alpha 2\beta 1$ and $\alpha 5\beta 1$).

On the luminal side, endothelium is exposed to blood elements and circulating molecules such as cytokines and bacterial products. Engagement of endothelial receptors by these humoral factors activates a well-described series of responses, including the recruitment and transmigration of leukocytes and changes in endothelial cell coagulant activity (see Chapters 49 and 125).

Biomechanical forces resulting from pulsatile blood flow have been shown to mediate striking changes in endothelial morphology and metabolism. Vessels must withstand three types of physical forces: radial distension (tension), longitudinal stretch, and tangential shear stress. In response to unidirectional laminar flow (shear stress), endothelial cells reorganize their cytoskeletal architecture, rearrange focal contacts at the basal surface, and align in the direction of flow. After exposure to physical forces, some endothelial cell responses occur within seconds, such as activation of potassium channels and increased release of nitric oxide (NO), resulting in vasodilation. Other responses are related to changes in gene expression and occur within hours. Whereas unidirectional laminar flow at physiological levels is atheroprotective, disturbed flow at arterial branchpoints and bends predisposes to atherosclerotic plaque formation and thrombosis (see Chapter 142). Disturbed flow, which interferes with laminar shear stress signals, induces vascular pathology by differentially regulating mechanosensitive transcription factors that modulate inflammation, mitochondrial function, and glucose metabolism among other functions.[21,22]

Endothelial cells directionally secrete ECM proteins, such as collagens, elastin, fibronectin, laminins, and proteoglycans, to the abluminal face. The composition of the subendothelium varies depending on location in the vascular tree, age, and disease states. Endothelial cells bind to the ECM via integrins that link and integrate matrix proteins to the cytoskeleton at sites referred to as *focal contacts*. The integrins detected in resting endothelium include $\alpha 6\beta 1$, $\alpha 5\beta 1$, $\alpha 2\beta 1$, and $\alpha v\beta 3$. The ECM serves several important functions including: (1) barrier to macromolecules in the event of disruption of the endothelium; (2) sequestration of growth factors and mediation of high-affinity binding to endothelial cells (e.g., heparan sulfate binds to fibroblast growth factor [FGF]); (3) counter-structure for the binding of endothelial cell integrins, and (4) presentation of a prothrombotic surface that initiates coagulation after injury.[23]

Binding of endothelial cells to the ECM serves at least four purposes: (1) provision of a physical scaffold, or as a haptotactic agent, to induce endothelial cell migration[11]; (2) induction of integrins clustering at focal adhesion contacts to activate signaling cascades that promote survival or differentiation; fibronectin and vitronectin provide survival signals, whereas laminins signal differentiation; (3) maintenance of cell shape through integrin-mediated cell spreading provides an antiapoptotic signal independent of direct integrin-initiated signal transduction; and (4) anchoring the cell, thereby providing a mechanism whereby blood flow at the luminal surface of the endothelium creates shear stress, which transmits signals to cells.[24]

Despite their common features, quiescent endothelial cells in vivo represent heterogeneous phenotypic populations.[17] Endothelial cells from veins and arteries and from capillaries of different organs demonstrate structural, functional, and molecular heterogeneity.[17] Exposure to various physical forces and the different functions served by vessels of different caliber are reflected in different endothelial phenotypes. Intriguingly, phenotypic heterogeneity also exists between neighboring endothelial cells exposed to the same extracellular environment.[25,26] Matrix proteins, soluble factors from the organ, or heterotypic contacts with parenchymal cells, pericytes or smooth muscle cells are believed to be important factors in specifying endothelial cell phenotype. Conversely, increasing evidence indicates that endothelial cells in turn provide instructive morphogenic cues during organogenesis and in adults.[27] Specific examples of microvessels found in hematopoietic tissues are discussed in the following sections.

High Endothelial Venules

Lymphocyte migration into secondary lymphoid sites, such as lymph nodes, Peyer's patches, and chronically inflamed nonlymphoid tissues, occurs at specialized postcapillary venules called *high endothelial venules* (HEVs).[28] The endothelial cells of these venules exhibit a plump morphology, display intense biosynthetic activity, and are encircled by a continuous thick basal lamina formed from ECM components produced by surrounding pericyte-like cells called *fibroblastic reticular cells*. HEV endothelial cells express tissue-specific adhesion molecules and secrete a thick adhesion molecule-containing glycocalyx. These HEV adhesion molecules are referred to as addressins and comprise the L-selectin ligands mucosal addressin cellular adhesion molecule 1 (MAdCAM-1), glycosylation-dependent cellular adhesion molecule 1 (GlyCAM-1), endomucin, and nepmucin. Other HEV receptors implicated in lymphocyte trafficking include $\alpha 4\beta 7$ integrin, CD34, the chemokine receptor DARC (Duffy antigen receptor for chemokines) and the antiadhesive matrix protein Hevin. In addition to recruitment of immune cells, HEV can also influence the outcome of the immune response.[29]

Endothelium of Bone Marrow Sinuses

BM sinus endothelial cells are flat with loose interdigitated junctions and discontinuous basal lamina and are programmed to regulate the egress of hematopoietic cells. For example, if a red blood cell (RBC) that still is nucleated begins to enter the circulation, the body of the cell is allowed to cross and is released as a reticulocyte, while the nucleus is retained extravascularly. Adventitial reticular cells (similar to pericytes) also play an important role in controlling hematopoietic cell egress, and CXCL12 (SDF-1)–abundant reticular cells may also participate in hematopoietic stem cell maintenance.[30] Most quiescent hematopoietic stem cells in the mouse are closely associated with marrow sinusoids, although it is possible that some are also present in a periarteriolar location. CXCL12 is highly expressed in endothelial cells, and interactions with chemokine receptor CXC-chemokine receptor (CXCR)4 are essential for stem cell homing, mobilization, and transendothelial migration into the BM. The CXCR4 antagonist, Pleraxifor, is used to mobilize stem cells for autologous transplantation in patients with lymphoma or myeloma.[31] Vascular cell adhesion molecule 1 (VCAM-1) expressed on BM endothelial cells appears to be the major BM addressin for hematopoietic progenitor cells expressing VLA-4 (α4β1 integrin). Endothelial selectins have also been implicated in promoting hematopoietic stem and progenitor cell homing to the BM. Blockade or genetic targeting of E-selectin inhibits niche-mediated pro-survival signaling of acute myeloid leukemia (AML) blasts and synergizes with chemotherapy (see Chapter 60). Clinical trials with the small-molecule E-selectin mimetic Uproleselan (GMI-1271) are under way in AML.[32] Factors such as CD44 and matrix metalloproteinases (MMPs) and mechanical factors such as cytoskeletal rearrangement are also key to the homing process related to the endothelium.

PHYSIOLOGIC FUNCTIONS OF THE ENDOTHELIUM

Endothelium as a Barrier

The microvessels act to exchange material brought to tissues through circulation. The movement of lipophilic and low-molecular-weight hydrophilic substances between blood and tissue is virtually unimpeded (except for the brain), but the vessels are selectively permeable to macromolecules. This semi-selective barrier is necessary to maintain the fluid balance between intravascular and extravascular compartments, yet antibodies, hormones, cytokines, and other molecules must have access to the interstitial space to exert their function.

The movement of macromolecules across the vessel wall is governed by (1) hydrostatic and oncotic pressure gradients; (2) physicochemical properties of the molecule, such as size, shape, and charge; and (3) properties of the barrier. The barrier of the vessel wall is formed by the cellular components, endothelial cells, and pericytes, as well as by the charge and compactness of the matrix components, glycocalyx, and basement membrane. Macromolecules can pass either directly through the endothelial cell (transcellular path) or between adjacent endothelial cells (paracellular path).[33]

Although water mainly moves across endothelium paracellularly, a significant proportion (≤ 40%) uses the transcellular route and water-transporting membrane channels, the aquaporins. Macromolecular transport into cells can proceed by receptor-mediated systems, such as clathrin-coated pits, in which the molecules usually are targeted to the lysosome but may be transported through the cell. Caveolae are 50 to 100 nm membrane invaginations that are abundant in capillary endothelial cells, and participate in transcytosis, as well as in translocation of glycosylphosphatidylinositol-linked proteins into the cytoplasm and in transmembrane signaling. The known leakiness of tumor microvasculature led to the identification of a structure designated the vesiculovacuolar organelle (VVO).[34] These organelles are clusters of interconnecting uncoated vesicles and vacuoles that span the entire thickness of the vascular endothelium, thereby providing a transendothelial connection between the vascular lumen and the extravascular space. Their function is enhanced by vascular endothelial growth factor (VEGF), which is known to increase the permeability of vessels.

During inflammation, binding of neutrophils to the endothelium results in the generation of oxidants that can induce endothelial cell injury and increase permeability. Upon adhesion of neutrophils to the endothelium, leukocyte CD18 (β2 integrin)-mediated signals trigger the release of the neutrophil cationic protein called *heparin-binding protein/CAP37/azurocidin*, which in turn induces formation of gaps between endothelial cells and macromolecular efflux. Thrombin, a crucial hemostatic enzyme and inflammatory mediator, can increase endothelial permeability by several mechanisms resulting from activation of its receptor on endothelial cells.[33] Both an increase in transcellular vesicular and paracellular permeability play a role. The contraction and retraction of endothelial cells are accompanied by “loosening” of intercellular junctions and focal integrin contacts with the ECM. An increase in paracellular permeability results from post-translational modification of components of junctional proteins such as claudins and VE-cadherin. Thrombin may also alter the repulsive effect of the negatively charged glycocalyx. Pericyte contractility has been hypothesized as an additional mechanism for increasing permeability in inflammatory states.[33]

Endothelium as a Non-Thrombogenic Surface

The molecular mechanisms of hemostasis and thrombosis are addressed in Chapters 121 and 125. This section places the endothelium in the context of these processes, as shown in Fig. 122.1. Normal unperturbed endothelium presents a non-thrombogenic surface to

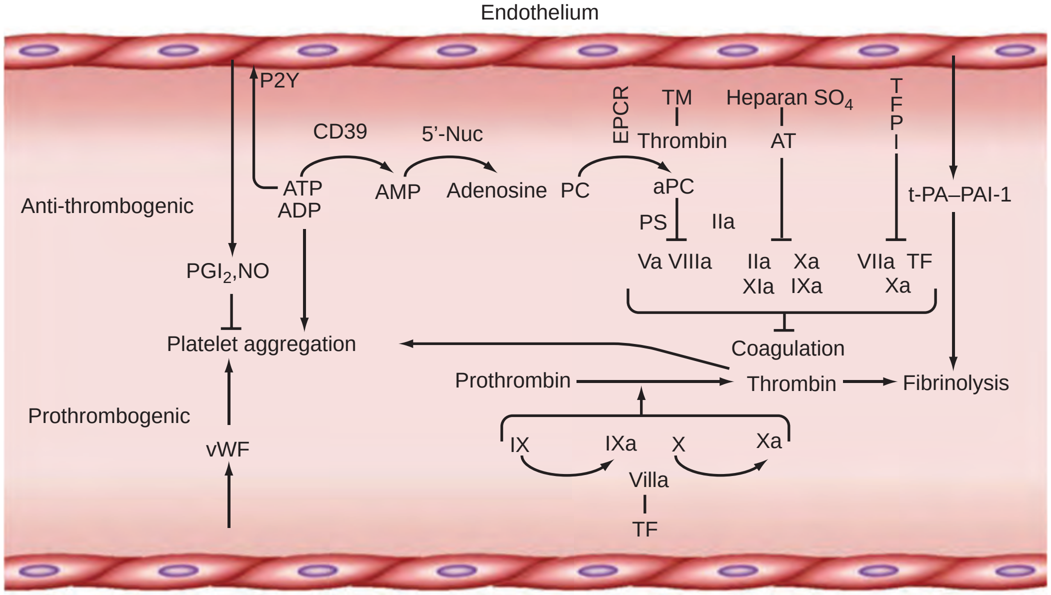

Figure 122.1 ENDOTHELIAL CELLS AS A PART OF THE HEMOSTATIC SYSTEM. In health endothelial cells expose antithrombogenic luminal surfaces due to several mechanisms, including modulation of platelet activity and the expression of tissue factor pathway inhibitor (TFPI) (see text). Perturbation of endothelial cell homeostasis by inflammation or injury may trigger the exposure of procoagulant subendothelial matrix, as well as procoagulant properties such as expression of tissue factor (TF), resulting in activation of the clotting cascade with resultant thrombin generation and activation of platelets (see text).

the circulation by inhibiting platelet aggregation, preventing the activation and propagation of coagulation, and enhancing fibrinolysis.[24] Conversely, when inflamed and injured or under conditions of disturbed flow, the endothelium may become thrombogenic.[35]

When near endothelial cells, platelets become unresponsive to agonists. This inhibition of platelet aggregation is accomplished by secretion of prostacyclin (prostaglandin I_2 [PGI_2]) and NO and by surface expression of an ecto-adenosine phosphatase (ADPase)/CD39/nucleoside triphosphate diphosphohydrolase (NTPDase-1). Prostacyclin is synthesized mainly by vascular endothelial and smooth muscle cells as a product of arachidonic acid metabolism. It inhibits platelet activation, secretion, and aggregation, as well as monocyte interaction with endothelial cells. It also causes vascular smooth muscle cell relaxation. NO also has a wide range of functions, including inhibition of platelet adhesion, activation, and aggregation. Most of the NO released from endothelial cells is elaborated abluminally, where it acts on the smooth muscle cell to cause vasodilation. However, some NO may enter the lumen and diffuse into platelets. Prostacyclin and NO can act synergistically to reverse platelet aggregation. The released platelet agonist, ADP, can be inactivated by endothelial membrane-associated CD39. Metabolism of ATP and ADP to adenosine monophosphate (AMP) by CD39 eliminates platelet recruitment and returns platelets to their resting state. Adenosine, which is generated by hydrolysis of AMP by ecto-5′-nucleotidase, inhibits platelet aggregation and promotes vasodilation. ATP/ADP can stimulate purinoreceptors on endothelial cells, resulting in the synthesis and release of PGI_2 and NO.[36]

Endothelial cells use three main pathways to inhibit thrombin generation and limit coagulation (see Chapters 121 and 125)[37]:

1. Antithrombin system: Heparan sulfate proteoglycans are secreted onto the luminal surface of endothelial cells and into the subendothelium. Heparan sulfates are capable of binding and activating antithrombin (AT), thereby accelerating inactivation of several procoagulant serine proteases, including thrombin, factor Xa, and factor IXa.
2. Protein C system: Thrombomodulin on the surface of endothelial cells binds thrombin. This coupling inhibits the coagulant properties of thrombin and increases its affinity for protein C, which it cleaves and activates. Activation of protein C by the thrombin–thrombomodulin complex is augmented by its binding to the endothelial cell protein C receptor (EPCR). Protein S, synthesized primarily by the endothelial cell, acts as a cofactor for activated protein C (APC). Independent of protein C, free protein S can inhibit the prothrombinase and intrinsic tenase complexes and interact directly with factors Va and VIIIa.
3. Tissue factor pathway inhibitor (TFPI): TFPI is a Kunitz-type serine protease inhibitor that modulates TF-initiated coagulation. TFPI binds to and directly inhibits the tissue factor (TF)–factor VIIa–factor Xa complex. It is mainly produced by and bound to endothelial cells, likely to surface glycosaminoglycans. There is also a plasma pool bound to low-density lipoprotein.

If coagulation occurs despite the many anticoagulant mechanisms, endothelial cells also provide proteins to promote fibrinolysis. Endothelium is a major source of tissue type plasminogen activator (t-PA). Approximately 40% of t-PA is bound to its inhibitor, PAI-1, which is also secreted by endothelial cells. Stresses such as exercise, acidosis, hypoxia, shear forces, increased venous pressure, and thrombin cause the release of t-PA, which converts plasminogen to plasmin, the key effector of fibrinolysis. Receptors for plasminogen and t-PA are present on the endothelial cell surface, enabling localized fibrinolytic activity.

Although intact endothelium is necessary to maintain blood in a fluid state and inhibit coagulation under normal conditions, injured endothelium can rapidly downregulate its anticoagulant functions and become procoagulant even without the overt vascular damage that occurs with trauma, surgery, or viral infection. Tissue injury or vascular pathology also leads to exposure of the underlying matrix, which is procoagulant by virtue of its binding to, and activation of platelets. Apoptotic endothelial cells become procoagulant through exposure of phosphatidylserine on their surfaces[38] and increased thrombin formation. These effects coupled with platelet adhesion to the injured endothelium contribute to thrombosis in diverse diseases.[37]

Even without endothelial death, perturbation of the vascular lining by inflammatory mediators converts the endothelium from a non-thrombogenic to a procoagulant surface because of downregulation of anticoagulant properties as well as induction of a procoagulant phenotype. Acute inflammation is associated with increased release of vWF, platelet-activating factor (PAF), and fibronectin, all of which may potentiate thrombus formation. Tumor necrosis factor (TNF), IL-1, and lipopolysaccharide increase endothelial cell expression of PAI-1 and decrease t-PA expression, thereby attenuating fibrinolysis, and downregulate thrombomodulin. Although they induce TF expression by cultured endothelial cells, evidence that they induce TF expression by endothelial cells in vivo is limited. *Instead*, circulating microparticles (also known as extracellular vesicles) generated by leukocytes, vascular or cancer cells have been shown to be a source of blood-borne TF and to contribute to coagulation. Although most microparticles are derived from platelets, RBCs, and monocytes, endothelial-derived microparticles may be an important source of circulating TF under conditions of massive activation.[39]

Endothelial Control of Vascular Tone

Vascular tone is orchestrated primarily by a balance between endothelium-derived vasodilators (NO, PGI_2, and various endothelium-derived hyperpolarizing factors [EDHFs]) and vasoconstrictors (endothelin-1 [ET-1], thromboxane [TXA_2] and superoxide).[40] In addition to inhibiting platelet aggregation, NO and PGI_2 serve as vasodilators. NO is produced by the conversion of L-arginine to L-citrulline by NO synthase (NOS). Three NOS genes exist, of which an inducible form (iNOS/NOS2) and a constitutively active endothelial form (eNOS/NOS-3) are expressed in endothelial cells. NOS2 may be responsible for the uncontrolled vasodilation seen in septic shock. NO release through NOS3 activation, mainly by unidirectional laminar flow-induced shear stress, is crucial for maintaining basal vasodilation. The action of NO on platelets (antiaggregatory), endothelial cells, and smooth muscle cells (relaxation) is caused by activation of guanylyl cyclase and formation of cyclic guanosine 3′,5′-cyclic monophosphate. Whereas NO is unstable, the formation of *S*-nitrosothiols in the presence of oxygen and thiols provides a stable reservoir of NO. Deoxygenation is accompanied by an allosteric change in *S*-nitrosohemoglobin that releases the NO group, thereby relaxing blood vessels and enabling sufficient blood flow to meet local oxygen requirements. Hemoglobin is a scavenger of NO, which may account for the vasoconstriction observed with the administration of cell-free, hemoglobin-based, RBC substitutes.

In addition to its antithrombotic role (above) endothelial PGI_2 acts locally to counterbalance the vasoconstriction induced by thromboxane A_2 (TXA_2). Whereas PGI_2 transduces a cellular signal by increasing the levels of cyclic AMP (cAMP), TXA_2 signals via the phosphoinositol pathway and lowers cAMP levels (see Chapter 123). The synthesis of prostaglandins is catalyzed by the action of cyclooxygenases (COX-1 and COX-2) on arachidonic acid. Aspirin irreversibly inhibits COX in both platelets and endothelial cells (see Chapters 123 and 124). However, its clinical effect is mainly exerted on platelets, which cannot synthesize new COX. Therefore, TXA_2 synthesis recovers only when new platelets enter the circulation, while endothelial COX restores PGI_2 levels within a few hours. In addition, platelets encounter aspirin before it is deacetylated by the liver and diluted by the venous circulation. The balance between the activity of PGI_2 and TXA_2 is important for vessel wall homeostasis, as evidenced by the fact that selective COX-2 inhibitors, which decrease the production of PGI_2 without affecting the production of TXA_2, increase the risk for cardiac events.

Endothelial cells release other relaxing factors (EDHFs), which act by increasing the membrane potential of smooth muscle cells. These factors comprise a variety of constitutive and inducible effectors including calcium-activated potassium channels, various cytochrome P450 and 15-lipoxygenase derived arachidonic acid metabolites, H_2O_2, and C-type natriuretic peptide.[41]

Endothelin 1 (ET-1) is a 21-amino acid peptide released preferentially at the abluminal surface of endothelial cells that exhibits potent vasoconstrictor activity. Of the three known ETs, only ET-1 is produced by endothelial cells. At least two receptors (ET-A and ET-B) bind all three ETs. Whereas ET-A is abundantly expressed on smooth muscle cells, ET-B is predominantly expressed on endothelial cells. The vasoconstrictor activity of ET-1 is preferentially mediated by ET-A G-protein–coupled receptors on smooth muscle cells. Engagement of the ET-B receptor on endothelial cells by ET-3 may paradoxically cause transient vasodilation. ET-1 may contribute to pregnancy-induced hypertension, reperfusion injury after ischemia, and pulmonary arterial hypertension. The dual ET receptor antagonist bosentan, and ET-A antagonist ambrisentan have been approved for treatment of the latter disease.

Another regulator of vascular tone is the superoxide anion. The source of this free radical may be the endothelium itself or inflammatory cells that have been recruited to sites of injury or inflammation. Interaction of superoxide radicals with NO produces peroxynitrite and reduces the concentration of NO. Peroxynitrite can oxidize low-density lipoprotein (LDL) and deleteriously modify other proteins, thereby causing endothelial dysfunction. Increased production of superoxide inhibits the synthesis of PGI_2 but not TXA_2.

The endothelium expresses angiotensin-converting enzyme (ACE) on its surface; this enzyme converts angiotensin I to angiotensin II, a potent vasoconstrictor. The interaction between ET, angiotensin II, and α-adrenergic agonists contributes to the pathogenesis of hypertension. An altered balance of the vasoactive substances described in this section has been proposed as a cause of endothelial dysfunction and the attendant vascular pathology observed in atherosclerosis, hypertension, and diabetes mellitus (see Chapter 142). Alteration of vascular function in these diseases may then perpetuate endothelial dysfunction and, consequently, worsen disease.[40]

INTERACTION OF BLOOD CELLS WITH THE VESSEL WALL

Leukocytes

In the absence of an inflammatory stimulus, neutrophils circulate freely and do not interact with the endothelium. This contrasts with continuous, low-level physiologic traffic of monocytes and lymphocytes across the vessel wall. Monocytes emigrate from the bloodstream to develop into tissue macrophages that may exhibit tissue- or organ-specific functions. To maintain immune surveillance of tissue, lymphocytes recirculate between blood and lymphatics, gaining entrance to the latter at the high endothelial venule of postcapillary venules in lymphoid tissue.[42]

Intravital microscopic studies have established a sequence of events involved in leukocyte emigration at extravascular sites of inflammation. Under conditions of flow, leukocytes first tether to, and then roll along, the endothelium of postcapillary venules adjacent to the site of inflammation. Some of the rolling leukocytes are activated and adhere firmly. The adherent leukocytes migrate along the endothelial surface

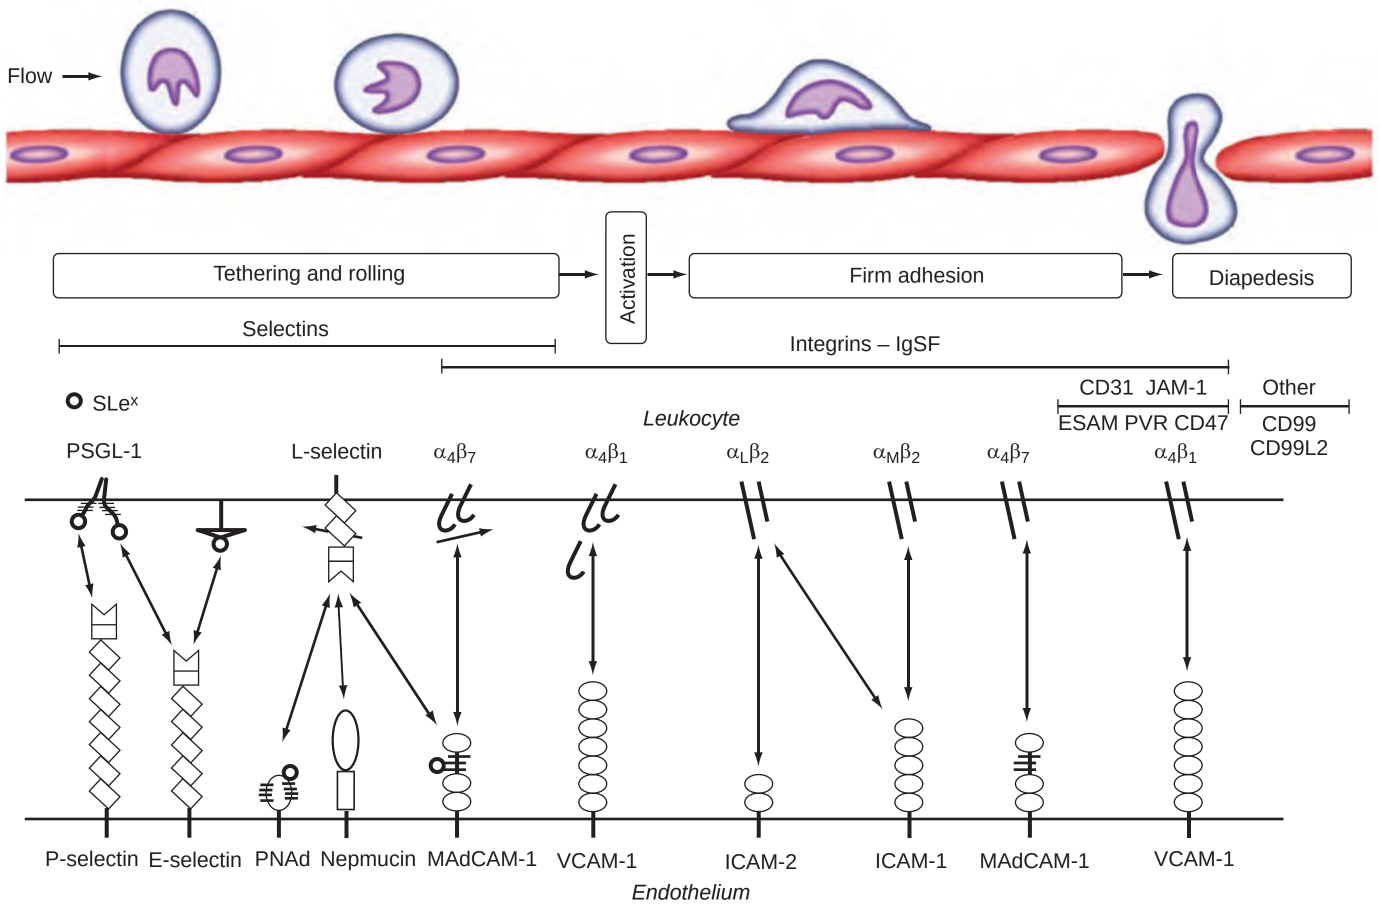

Figure 122.2 MOLECULAR MEDIATORS OF LEUKOCYTE-ENDOTHELIAL INTERACTIONS. The four-stage model of leukocyte-endothelial interactions (tethering, rolling, firm adhesion, and diapedesis) is predicated on diverse modes of adhesive interactions between the surfaces of the respective cells. These interactions are mediated by several classes of adhesion molecules including selectins, immunoglobulin family cell adhesion molecules and integrins (see text). *ESAM*, Endothelial cell-selective adhesion molecule; *ICAM-1*, intercellular adhesion molecule 1; *ICAM-2*, intercellular adhesion molecule 2; *JAM-1*, junctional adhesion molecule A; *MAdCAM-1*, mucosal addressin cell adhesion molecule 1; *PNAd*, N-terminal asparagine amidase; *PSGL-1*, P-selectin glycoprotein ligand 1; *PVR*, poliovirus receptor; *SLex*, sialyl-Lewis X antigen; *VCAM-1*, vascular cell adhesion molecule 1.

and diapedese between endothelial junctions to enter the extravascular tissue.[43] These steps in emigration (i.e., tethering, rolling, activation, firm adhesion, and diapedesis) are also involved in lymphocyte emigration at HEVs.[44] They result from the interaction between distinct leukocyte counterreceptors and endothelial receptors in an adhesion cascade (Fig. 122.2).[45,46] Rolling is observed only under flow conditions and is the consequence of shear forces acting on the leukocyte and adhesive interactions between selectin receptors and their glycoconjugate counter structures. It is initiated primarily by activation of the endothelium by extravascular stimuli such as bacterial-derived products or by endogenous mediators produced by the endothelium or cells in tissue. Early on, rolling is mediated by endothelial P-selectin, which is rapidly translocated from Weibel-Palade bodies to the luminal surface, and L-selectin on leukocyte microvilli. E-selectin is involved only at later time points because it is not constitutively expressed by endothelium but rather is induced over hours by de novo synthesis.

For leukocytes to circulate freely, their integrin receptors must be minimally adhesive, but they also must be able to rapidly increase binding at sites of inflammation. After tethering to endothelium by selectin interactions, leukocyte integrin receptors are activated by endothelial membrane-expressed PAF, endothelial membrane-bound chemokines, or locally secreted chemoattractants. Activation of leukocyte integrins involves changes in receptor affinity or affinity-independent receptor clustering, thereby promoting firm adhesion to endothelial ligands, which are members of the immunoglobulin gene superfamily (IgSF). These IgSF ligands are constitutively expressed (ICAM-1, ICAM-2), further upregulated (ICAM-1), or induced (VCAM-1) by inflammatory mediators. Subsequent leukocyte migration over the endothelium requires reversible adhesion caused by cyclic modulation of receptor avidity.

There are several caveats regarding the multistep model of initial selectin-mediated rolling and subsequent integrin-mediated firm adhesion. First, selectin-mediated rolling is not a prerequisite for emigration under conditions of reduced flow, as might occur at sites of inflammation. Second, the model was developed from observations in the systemic microcirculation where leukocyte emigration occurs in postcapillary venules under relatively low shear forces. However, selectins do not appear to play a major role in neutrophil emigration in the pulmonary microcirculation, where emigration occurs predominantly in capillaries, or in the liver microvasculature, where leukocytes emigrate primarily in sinusoids. Third, under some conditions, leukocytes can tether and roll via receptors other than selectins and α4 integrins (e.g., CD44 or VAP-1). Finally, several other adhesion pathways have been implicated in leukocyte adhesion to endothelium in vitro, and their roles in the adhesion cascade in vivo remain uncertain.[47]

While migrating on the endothelial surface, some leukocytes encounter an intercellular junction, diapedese between endothelial cells, enter extravascular tissue, and then migrate to the sites of inflammatory or immune reaction. This process depends on leukocyte integrin interactions with endothelial Ig superfamily ligands and on several junctional proteins, including PECAM-1 (CD31), JAM-1, CD99, CD99L2, ESAM, PVR, and CD47.[47–49] Diapedesis involves signaling by the leukocyte to the endothelial cell that triggers the opening of endothelial cell junctions. In some cases, leukocytes may emigrate directly through the body of an endothelial cell.[47]

Leukocyte recruitment is terminated by several mechanisms. Whereas E-selectin and P-selectin are removed from the endothelial cell surface by endocytosis, L-selectin is cleaved from leukocytes by a membrane protease. Decay of cytokine, chemokine, or chemoattractant generation leads to gradual resolution of endothelial adhesion molecule expression and integrin activation. Locally expressed mediators, such as NO, TGFβ, and Fas ligand, also inhibit further leukocyte adhesion to endothelium.[47]

The adhesion molecules involved in leukocyte trafficking from the bloodstream to tissue have emerged as important therapeutic targets. Extensive preclinical studies showed that blockade of leukocyte or endothelial adhesion molecules was efficacious in diverse disease models, prompting the development of adhesion antagonists. In spite of the seemingly sound biology, clinical development of these agents was largely unsuccessful, and progressive multifocal leukoencephalopathy, a rare viral infection of the central nervous sytem (CNS), was observed in patients treated with the α4-integrin antagonist natalizumab. However, approval of two integrin antagonists: efalizumab for treatment of psoriasis and natalizumab for treatment of multiple sclerosis[50] suggests a potential benefit for specific indications.

Platelets

Like neutrophils, non-activated platelets do not interact with unperturbed endothelium (see Chapter 124). After a vascular injury that produces endothelial denudation or retraction, platelets rapidly adhere to the exposed subendothelium. As discussed in greater detail in Chapters 123 and 124, at high shear rates, this initial adhesion does not require platelet activation and involves platelet glycoprotein Ib/V/IX (GPIb–V–IX) binding to vWF in the subendothelial matrix and platelet glycoprotein VI (GPVI) binding to collagen in the injured arterial wall. Platelet activation occurs after adhesion, leading to platelet spreading mediated by integrin receptor binding to matrix components and aggregation mediated by fibrinogen binding to activated GPIIb/IIIa (αIIbβ3).

In the context of inflammation, platelets are the first cells to adhere to the endothelium in postcapillary venules, where they recruit neutrophils and direct them through the endothelial barrier while maintaining vascular integrity. This process is mediated through cell-cell interactions and the release of chemokines.[51] Platelets can bind directly to activated endothelium in vivo via endothelial P-selectin and PECAM-1 and can roll on venular endothelium via interaction of platelet GPIbα with endothelial P-selectin. Platelets bind to HEVs in vivo via platelet P-selectin. In vitro, platelets adhere to intact endothelium via a platelet GPIIb/IIIa-dependent bridging mechanism involving platelet-bound adhesive proteins and the endothelial cell receptors ICAM-1, αVβ3 integrin, and GPIbα. Platelet adhesion to intact endothelium via these various pathways may contribute to thrombus formation in the circulation and may provide a link between thrombosis and inflammation in diseases such as atherosclerosis (see Chapter 142). Platelet-endothelial interactions also may contribute to the pathogenesis of thrombotic thrombocytopenic purpura (see Chapter 132). Normally, ultra-large vWF multimers remain attached to endothelium via P-selectin until they are cleaved by the plasma metalloproteinase ADAMTS-13. Failure of vWF multimer cleavage due to a deficiency of ADAMTS-13 may lead to spontaneous platelet adhesion to the endothelium and microvascular thrombosis in thrombotic thrombocytopenic purpura.[52]

Red Blood Cells

RBCs normally do not bind to endothelium unless damaged by sickle cell disease or infection with malaria parasites. The binding of sickle cells to postcapillary endothelium with secondary trapping of poorly deformable cells is thought to be an important pathogenic factor in vasoocclusive events (see Chapter 42).[53] Several interactions between sickle RBC receptors and endothelial ligands have been described, including α4β1/VCAM-1; α4β1/Lutheran blood group (basal cell adhesion molecule); and ICAM-4/αVβ3. The adhesive proteins thrombospondin (TSP-1) and vWF promote adhesion by serving as bridging factors between various sickle RBC and endothelial adhesion molecules. In addition to direct adhesion to endothelium, sickle RBC binding to adherent leukocytes appears to be an important mechanism for vascular occlusion in sickle cell disease.[54] Further, microparticles generated primarily from RBC, as well as free Hb, heme and iron released during hemolysis can activate endothelial cells and neutrophils to increase adhesion, potentially accelerating vasoocclusion.[55,56] Like leukocyte adhesion to endothelium in inflammatory and immune diseases, drugs targeting sickle RBC adhesive interactions with endothelial cells or leukocytes may prove useful in preventing or treating vaso-occlusive crises (see Chapter 43).[57,58]

Among human malarial parasites, only *Plasmodium falciparum* modifies the surface of the RBCs such that asexual parasites and gametocytes can adhere to the vascular endothelium. The binding of trophozoite- and schizont-infected RBCs to endothelium not only allows the parasite to escape destruction in the spleen but also may contribute to the pathogenesis of cerebral malaria. Multiple endothelial adhesion receptors have been implicated in mediating cytoadherence of infected RBCs, including P-selectin, ICAM-1, VCAM-1, and CD36.[53,59]

ENDOTHELIAL CELL ACTIVATION AND DYSFUNCTION

The endothelium is a dynamic and heterogeneous organ that responds to diverse stimuli, ranging from coagulation proteins and cytokines to hemodynamic forces and growth factors.[17] Activation of endothelial cells induces a complex proinflammatory and prothrombotic phenotype as well as expression of certain cytoprotective genes. Multiple transcription factors, particularly nuclear factor-κB (NFκB) and early growth response 1 (EGR-1), regulate these responses. Endothelial activation undoubtedly is an important event in host defense and repair, but it also may contribute to the pathogenesis of diverse disease states, ranging from sepsis to atherosclerosis.[60]

Endothelial dysfunction is characterized by a reduction in the bioavailability of vasodilators, particularly NO, leading to impairment of endothelium-dependent vasodilation, or by an increase in endothelium-derived contracting factors. Endothelial dysfunction is prominent in atherosclerosis but also has been described in diabetes, preeclampsia, hypertension, uremia, viral infections, and other diseases. In a broader sense, endothelial dysfunction encompasses proinflammatory and procoagulant changes, as well as apoptotic cell death.[61]

Several noninvasive approaches for assessing endothelial function have been developed. Endothelial vasodilatory responses can be evaluated by high-resolution ultrasound measurement of flow-mediated vasodilation or by using plethysmography to monitor changes in forearm blood flow during reactive hyperemia. Endothelial activation can be assessed in plasma by measuring the levels of biomarkers such as soluble endothelial adhesion molecules (e.g., sVCAM-1, sICAM-1, sE-selectin), endothelial coagulation proteins (e.g., vWF and thrombomodulin), or endothelial extracellular vesicles (EVs/MPs). The detection of circulating endothelial cells reflects significant vascular damage or cell death.[61]

A particularly aggressive form of endothelial activation and dysfunction has been noted with the emergence of zoonoses by the coronaviruses, SARS-CoV, MERS-CoV, and most virulently with SARS-CoV2, which causes COVID-19.[62,63] SARS-CoV-2 requires two receptors, ACE2 and the transmembrane protease TMPRSS-2, to bind and invade cells. Both receptors are expressed on the endothelium to varying degrees in different vascular beds. The endotheliopathy consequent to SARS-CoV-2 infection can result in vascular dysfunction, massive inflammation and coagulopathy.[64,65] Endothelial cells may be both an inducer and a target cell for coronavirus-induced cytokine release syndrome. The resulting impact on the integrity of the vasculature is clinically manifested in a subset of patients as stroke, thromboembolism, in situ thrombosis, or multiorgan failure. Immunothrombosis, which is the direct interaction of activated leukocytes with platelets and plasma coagulation factors, and endothelial apoptosis appear to contribute to the thrombotic events described in COVID-19. The nature of the underlying abnormality resembles a thrombotic microangiopathy, coupled with micro- and macrothrombosis and the induction of angiogenic responses in the affected vasculature.[64]

MOLECULAR REGULATORS OF VASCULAR GROWTH RESPONSES

Although vascular structures exhibit stability in adulthood, they are capable of anatomical changes through growth, remodeling, and regression. In this regard, the state of vascular networks is controlled by a web of intercellular communications, which are executed by soluble growth factors, adhesion molecules, ECM molecules, cell-cell contacts, the hemostatic system, various proteases, and the intercellular exchange of molecules (proteins, messenger RNA (mRNA), and microRNA).[2] A part of this circuitry entails the emission/uptake of EVs, including exosomes.[66] Of the involved mediators, some are essential for vascular growth and homeostasis, while others play more pleiotropic and context-dependent roles (see Table 122.1).[1,2,67]

Vascular Endothelial Growth Factors

Vascular endothelial growth factor-A (VEGF-A), which is also known as VEGF or vascular permeability factor (VPF), is indispensable for vascular development.[2,68,69] VEGF is the key member of a larger family of related polypeptides, including VEGF-B, VEGF-C, VEGF-D, VEGF-E, VEGFR-F, and placental growth factor (PlGF). Upon dimerization, these factors bind to their tyrosine kinase receptors (RTKs/VEGFRs), including VEGFR1/Flt-1, VEGFR2/KDR/Flk-1, and VEGFR3/Flt-4, often in conjunction with their neuropilin coreceptors (NRP1, NRP2),[70] as depicted in Fig. 122.3. For instance, VEGF-A interacts with VEGFR2, VEGFR1, and VEGFR3, whereas PlGF is selective for VEGFR1. The distribution of different VEGFRs on vascular (VECs) and lymphatic (LECs) endothelial cell subsets, as well as among endothelial progenitor cells (EPCs), hematopoietic, myeloid, and certain tumor cells, defines the known biologic activities of the various VEGF ligands. The effects of VEGF include stimulation of endothelial mitogenesis, migration, survival, morphogenesis, and vascular permeability (e.g., through formation of intercellular gaps, vesiculo-vacuolar organelles or transcellular structures know as *fenestrae*).[68] The signaling activity of VEGFR2 is crucial for these processes, whereas VEGFR1 is often expressed as a soluble splice variant (sFlt-1) that neutralizes VEGF (serves as a VEGF “sink”), thereby inhibiting angiogenesis.[2]

VEGF activity is also regulated by splicing of the corresponding mRNA, resulting in the generation of several protein isoforms, including VEGF121, VEGF145, VEGF165, VEGF189, and VEGF206 (designations based on the number of amino acids).[2] Alternative splicing leads to the formation of a series of proangiogenic (VEGF-A_{xxx}a) and antiangiogenic (VEGF-A_{xxx}b) VEGF isoforms, the former being biologically predominant.[71] VEGF-A isoforms differ in their cell association, solubility, and ability to bind heparinoids, or to interact with neuropilins, all of which define the formation of extracellular gradients and related biologic responses to these factors. In this regard, VEGF165 is an especially potent inducer of angiogenesis (see Fig. 122.3).

VEGF-C and VEGF-D stimulate the growth of lymphatics (lymphangiogenesis) via activation of VEGFR3, while VEGF-B and PlGF interact with VEGFR1 and are involved in vascular pathologies and inflammation.[2]

Platelet-Derived Growth Factors

This family of VEGF-related growth factors consists of four members: PDGF-A, PDGF-B, PDGF-C, and PDGF-D, the homo- or heterodimers of which interact preferentially with one of the three known cellular RTKs, namely, PDGFRα, PDGFRβ, and PDGFRγ, each endowed with different cellular functions. For example, PDGF-BB is expressed by endothelial cells and mediates their capacity to attract mural cells harboring PDGFRβ.[72]

Prokineticins

This group of factors consists of the endocrine gland vascular endothelial growth factor/prokineticin 1 (EG-VEGF/PK1) and prokineticin 2 (Bv8/PK2) secreted by *Bombina variegata*, both of which interact with their respective G-protein-coupled receptors on endothelial cells (PK-R1 and PK-R2). These mediators induce VEGF-like effects in endothelial cells and may render tumors resistant to VEGF inhibition.[73]

Angiopoietins and TIE Receptors

Angiopoietins (ANGs) are encoded by three different genes (ANGPT1, 2, and 4), and products of which interact with the tyrosine kinase with immunoglobulin-like loops and epidermal growth factor homology domains-2 (TIE2 or TEK), a receptor tyrosine kinase (RTK), which is preferentially expressed by endothelial cells and some myeloid cells (see Fig. 122.3). They are members of a larger family including mouse ortholog of ANGPT4 (ANGPT3) and seven angiopoietin like proteins (ANGPTL), many with still poorly defined functions.[74] A receptor related to TIE2 and known as TIE1, interacts with leukocyte cell-derived chemotaxin 2 (LECT2) during the process of sinusoid capillarization[75,76] and acts by modulating TIE2 activity. Among TIE2 ligands, angiopoietin 1 (ANG1) emanates from perivascular cells and serves as the main receptor agonist to stabilize endothelial–mural cell interactions and to promote endothelial cell survival, vascular quiescence, and the nonpermeable state. ANG2, which is produced by VEGF-stimulated endothelium, exerts the opposite effect and stimulates pericyte detachment, permeability, vascular growth, or regression, as well as lymphangiogenesis.[2]

Notch Pathway

Delta-like (Dll1, 3, and 4) and Jagged (1 and 2) are membrane-bound ligands that activate Notch receptors (Notch 1–4) on adjacent cells. During vascular development and growth, Dll4 and Jagged 1 are expressed by subsets of endothelial and mural cells, respectively, and regulate their distinct functions within the capillary outgrowths (sprouts), as depicted in Figs. 122.3 and 122.4. Dll1 is also involved in circumferential vascular enlargement (arteriogenesis).[77]

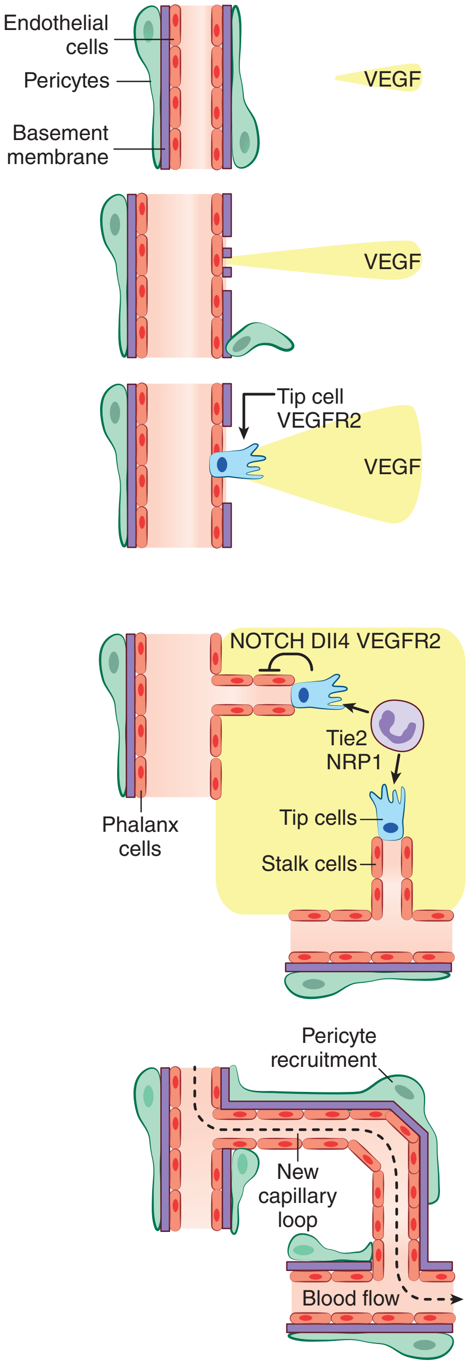
Ephrins and Eph Receptors

The arterial or venous identity of endothelial cells in the evolving microcirculation is preprogrammed by the expression of transmembrane guidance molecules, especially ephrin B2 and its EPHB4 receptor. Bidirectional signals emanating from these molecules, together with mechanosensory cues, govern the hierarchical arteriovenous vascular branching (*arborization*) that is essential for, and maintained by, proper blood flow. Other ephrins are implicated in endothelial–pericyte interactions and communication between blood vessels and tumor cells. They may also cooperate in VEGFR2 endocytosis and signaling.[2]

WNT and Guidance Factors

In addition to ephrins, several families of guidance molecules involved in the central nervous system also play important roles in vascular homeostasis and angiogenesis. Some of the crucial ligand-receptor pairs implicated in such interactions include WNT/Frizzled, Neuropilin (NRP)/Semaphorin, Slit/Robo, Sonic hedgehog (SSH)/Patched/Smoothened, and other pathways.[78,79] Some of the crucial effects of these interactions are exemplified by the role of WNT signaling in vascular permeability in brain tumors.[80]

Like the nervous system, the vasculature forms a highly ordered, branching network. The ordering of this patterned network is dependent on multiple attractive and repulsive cues, many of which are common to both the nervous and vascular systems.[81] As outlined in the following sections, the formation of new capillaries through the process of angiogenic sprouting involves the emergence of three distinct endothelial cell populations: the guiding cells (tip cells), following cells (stalk cells), and remaining cells (phalanx cells; see Fig. 122.4).[2]



Angiogenic gradient formation (“switch”)
Hypoxia, inflammation, oncogenic transformation
Increased expression of stimulators (VEGF)
Decreased expression of inhibitors

Endothelial (phalanx) cell stimulation
Basement membrane dissolution
Pericyte "drop out"
Circumferential extension (mother vessels)

Formation of endothelial tip cells
VEGF gradient sensing
Expression of tip cell markers
Metabolic adaptation (glycolysis)

Formation of endothelial sprouts
Directional migration of tip and stalk cells
Blockade of VEGFR2 expression on stalk cells
by tip cells via the Dll4/Notch pathway
Tip guidance (semaphorins, neuropilins, plexins, Robo4)

Extension of sprouts
Growth and migration of stalk cells and lumen formation

Myeloid cell–dependent anastomosis
Signalling by Tie2, Ang2, PlGF, PHD2, SDF-1a

Formation of new vascular loops
Connection and anastomosis of sprouts

Vascular maturation
Pericyte recruitment/vessel maturation (PDGFRb, Ang1)
Restoration of basement membrane (TIMPs, PAI-1)
Endothelial quiescence–phalanx cells (Notch)
Junction formation (VE-cadherin)
Anticoagulant surfaces

Blood flow
Resolution of hypoxia

Figure 122.4 SPROUTING ANGIOGENESIS. The change in the balance between angiogenesis stimulators and inhibitors (angiogenic switch) and especially the gradient of VEGF leads to sprouting angiogenesis. This process represents the core cellular program in formation of new capillary blood vessels from preexisting ones and begins with changes in the vessel wall (endothelial phalanx cells). The resulting formation of enlarged mother vessels, endothelial tip cells, proliferating stalk cells, capillary loops, and eventually anastomoses are depicted (details in the text[2]). *A*, Angiopoietin; *Dll4*, delta-like 4; *PAI-1*, plasminogen inhibitor; *TIMP*, tissue inhibitor of MMP; *VEGF*, vascular endothelial growth factor; *VEGFR*, vascular endothelial growth factor receptor.

Tip cells represent an important paradigm that illustrates the endothelial guidance apparatus. These cells express a distinctive profile of genes with substantially higher levels compared with stalk cells of platelet-derived growth factor (PDGF)-B, VEGFR-2, uncoordinated (Unc)5b, Delta-like (Dll)4, and VEGFR-3.[82] Whereas VEGF165 acts as an attractive cue to the tip cell of the endothelial sprout, Netrin-1 signals to Unc5b on the vasculature acting as a repulsive cue. Netrin-4 can also bind Neogenin, which in turn recruits and activates Unc5b to mediate repulsion. Interestingly, patterning and specification of small arteries along peripheral nerves in the skin of the embryonic limb involve nerve-derived VEGF; in other situations, neuronal patterning is dependent on the vasculature.[81,83] Thus, the congruent patterning of the neural and vascular systems likely is caused by the use of common signals and may require a cross-talk between the two systems.

Transforming Growth Factor β

Members of the transforming growth factor-β (TGFβ) family are multifunctional homodimeric peptides with diverse effects on cell proliferation, migration, differentiation, adhesion, and expression of cell adhesion molecules and ECM.[84] They are secreted as inactive precursors. After activation, they transmit signals to cells by binding to heteromeric complexes of type I and type II serine/threonine kinase receptors. In most cell types, the type I receptor engaged by TGFβ is the activin receptor-like kinase 5 (ALK5). However, in endothelial cells, TGFβ can bind and signal through ALK5 and ALK1. Contact between endothelial cells and periendothelial cells is required for the production of active TGFβ. Mice lacking TGFβ or TGFβ receptor type II exhibit similar defects in vasculogenesis and hematopoiesis. Endothelial proliferation is not affected, but poor contacts between endothelial and other cell layers in embryos of $TGF\beta^{-/-}$ mice result in a disorganized and reduced vascular network lacking capillary tubes. Mutations in two TGFβ receptors, ALK1 and the accessory TGFβ receptor endoglin, have been linked to the vascular disorder hereditary hemorrhagic telangiectasia. Disruption of TGFβ signaling likely plays a role in the telangiectasia seen in this disorder.[84]

Extracellular Matrix, Vascular Integrins, Cadherins, Cell Adhesion Molecules

Quiescent endothelial cells are anchored to the basement membrane, a structured layer of ECM composed mainly of laminin and collagen type IV. In contrast, growing (angiogenic) endothelial cells are surrounded by provisional ECM containing fibrin, vitronectin, fibronectin, and partially degraded collagens. Growth factors upregulate the expression of dimeric integrin receptors (αvβ3, αvβ5, α1β1, α2β1, α4β1, α5β1), which recognize specific motifs in ECM molecules (often the RGD sequence). Angiogenic growth factor receptors require integrin interactions for their signaling function.[2,85] The various functions of VE-cadherin/CD144, claudins (e.g., endothelial claudin 5) and connexins have been described earlier along with their role in endothelial cell interactions and adhesive communication with other cells.[5,86]

Structural and Functional Roles of the ECM During Vascular Growth Processes

Whereas interstitial collagens (e.g., collagen I) and provisional plasma-derived fibronectin–fibrin matrices stimulate endothelial tubular morphogenic events, laminin-rich matrices lead to endothelial differentiation and stabilization events.[87,88] Mice deficient in fibronectin die during embryogenesis and exhibit vascular defects. Type I collagen-deficient mice die of circulatory failure just before birth. Although most tumor vessels are covered by basement membrane, multiple structural abnormalities are noted in tumors consistent with ongoing vascular activation.[89] ECM proteins or their proteolytic fragments have been shown to inhibit angiogenesis.[1]

Adhesion Molecules Involved in Vascular Growth

Although it is universally accepted that integrins and integrin ligands function in angiogenesis, their exact actions remain unclear or debatable. In particular, substantial controversy surrounds the role of αvβ3 integrin.[90] Immunohistochemical studies localize this integrin to the tips of sprouting vessels. Neutralizing antibodies abrogate angiogenesis and induce vascular cell apoptosis in vivo, and inhibitory peptides or peptidomimetics blocking adhesive functions of integrin αvβ3 inhibit angiogenesis in a variety of animal models.[90] However, mice lacking αv show extensive angiogenesis, while both mice and humans (Glanzmann thrombasthenia) lacking β3 integrin also show normal angiogenesis.[91]

One of the integrin receptors for fibronectin, α5β1, has been shown to be necessary for vascular development, and α2β1 seems important for the formation of tubes by endothelial cells in vitro. However, there likely is a dynamic regulation of β1 integrins during angiogenesis because constitutive activation of this integrin inhibits endothelial sprouting in vitro and angiogenesis in vivo.[92] The junctional proteins VE-cadherin and PECAM-1, and possibly JAM-1, are expressed early in development and have a role in assembling the vasculature.[2]

Proteases

Proteases regulate the remodeling, growth, and invasion of new blood vessels. Some of these effects include the liberation of endothelial cells from their basement membrane confines, release of ECM-bound angiogenic growth factors, generation of regulatory peptides (e.g., angiogenesis inhibitors), clotting and fibrinolysis, intracellular signaling by protease-activated receptors, and numerous other steps involved in vascular maintenance and remodeling. For example, MMPs and their tissue inhibitors (TIMPs 1–4) participate in the controlled ECM/basement membrane breakdown that is required for invasiveness of the angiogenic endothelium.[93] The key enzymes in this group include: MMP-1, MMP-2, MMP-9, and MMP-14, coagulation factors (factor VIIa and thrombin) and their receptors (TF and PAR-1), plasminogen activators (u-PA) and their inhibitors (PAI-1), members of the disintegrin and metalloproteinase domain, and thrombospondin motif-containing families (ADAM and ADAMTS).[93,94]

Some of these effects are exemplified by the dissolution of subendothelial ECM by MMPs and heparanases, thus allowing endothelial cells to migrate at the initiation step of angiogenesis.[94,95] Matrix-bound growth factors are also released after ECM degradation. The balance between positive and negative regulators is the basis of tight control in this process. Tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), by generating plasmin, can activate collagenases and other MMPs. Plasminogen activator inhibitors (PAIs) may block angiogenesis at this step. The MMPs are required for angiogenesis, and the tissue inhibitors of MMPs regulate their function.[96]

PLEIOTROPIC REGULATORS OF VASCULAR GROWTH

In addition to "professional" regulators of blood vessel formation and growth processes, several molecules with more pleiotropic biologic activity serve as stimulators or inhibitors of structural changes in the vasculature, either directly or indirectly (e.g., as inducers of VEGF). Examples of these diverse effectors are listed in Table 122.1 and include certain growth factors (FGF1, FGF2, HGF, TGFβ), chemokines (IL-8/CXCL8, SDF-1/CXCL12), secreted ECM proteins (TSP1, TSP2), proteolytic ECM fragments (tumstatin, angiostatin), phospholipids (sphingosine 1 phosphate [S1P]), and several other molecules.[1] The effects of these regulators on angiogenesis and other vascular growth responses are mediated by intracellular signaling pathways, including GTPases (Ras), kinases (src, Akt, PKC), transcription factors (ERG, HIF, MYC), microRNA species (miR17–92, miR155), and other effectors (see Fig. 122.3).[2] Among several classes of growth factors, polypeptides and lipids that exert vascular growth stimulating activities of special interest are factors central to wound healing programs, in which vascular growth plays a key role. Those activities are exemplified by

TABLE 122.1 **Molecular Regulators of Vascular Growth and Remodeling**

Regulator	Main Receptor(s)	Biologic Activity
Angiogenic Effectors Central to Endothelial and Mural Cell Function		
VEGF-A/VEGF	VEGFR2 (VEGFR3, VEGF1), NRP1	Stimulator of angiogenic functions, migration and survival of ECs, including the formation of tip cells
VEGF-C	VEGFR3 (VEGFR2)	Stimulator of angiogenesis (ECs) and lymphangiogenesis (LECs)
Ang 1	Tie2	Positive regulator of endothelial-mural interactions, EC survival, and vessel maturation
Ang 2	Tie2	Negative regulation of endothelial-mural interactions, stimulator of lymphangiogenesis
Dll4	Notch	Inhibitor of tip cell formation
Jag1	Notch	Stimulator of tip cell formation
EphrinB2	EPHB4	VEGFR internalization/signaling, arterial identity, tube formation
PDGF-B	PDGFRβ	Recruitment of mural cells, vessel maturation
TGFβ1	TGFβRII	Differentiation of mural cells, ECM formation
Integrins (αv, β1, β5)	ECM proteins	EC survival, migration morphogenesis
Stimulators Involved in Pathologic Angiogenesis		
PlGF	VEGFR1	Stimulates angiogenesis by interaction with ECs and BMDCs
Acidic FGF (FGF-1)	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
Basic FGF (FGF-2)	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
FGF-3	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
FGF-4	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
IL-8	CXCR1	Stimulator of ECs and inflammatory cells
IL-6	IL-6R	Stimulator of inflammatory angiogenesis
TNFα	TNFR1 (p55)	EC stimulator and VEGF inducer
Bv8	GPCR	Stimulator of endocrine and tumor ECs
PD-ECGF/TP	Unclear	Stimulator of angiogenesis
Angiogenin	170-kDa receptor	Stimulator of angiogenesis and tRNAse
MMP9	ECM proteins	Matrix metalloproteinase that breaks down the ECM and releases angiogenic growth factors

Endogenous Angiogenesis Inhibitors

Inhibitor	Biologic Activity
TSP-1	Interacts with the CD36 receptor, integrins, and other proteins, causing growth inhibition and apoptosis of angiogenic ECs
Endostatin	Proteolytic fragment of collagen XVIII with antiangiogenic activity
Angiostatin	Proteolytic fragment of plasminogen with antiangiogenic activity
Tumstatin	Proteolytic fragment of collagen IV alpha 3 chain
sFlt-1/sVEGFR1	Soluble splice variant of VEGFR1 neutralizing VEGF and blocking VEGFR2 signaling
VEGF165b	Splice variants of VEGF with antiangiogenic activity
PEX	Inhibitor of EC invasion and MMP activity
IFNα (β)	Inhibits release of angiogenic growth factors

Ang (1,2), Angiopoietin; *Bv8*, *Bombina variegata* protein; *Dll4*, delta-like 4; *FGF*, fibroblast growth factor; *GPCR*, G-protein–coupled receptor; *IFN*, interferon; *IL-6*, interleukin 6; *IL-8*, interleukin 8; *Jag1*, Jagged 1; *MMP9*, matrix metalloproteinase 9; *PD-ECGF/TP*, platelet-derived endothelial cell growth factor/thymidine phosphorylase; *PDGF*, platelet-derived growth factor; *PlGF*, placenta growth factor; *TNFα*, tumor necrosis factor alpha; *TSP-1*, thrombospondin 1; *VEGF*, vascular endothelial growth factor. See text and references for details.

FGFs, inflammatory cytokines, coagulation factors, and EVs, all of which emerged as increasingly well-defined and often actionable elements in the circuitry driving vascular growth and pathology.[2,66,86]

Fibroblast Growth Factors

The FGF family of growth factors encompasses 22 members and 3 subfamilies (FGF1/2/5, FGF3/4/6, FGF7/10/22, FGF8/17/18, and FGF9/16/20) interacting with three receptor tyrosine kinases (FGFR1–3) and heparin sulfate proteoglycan (HSPG) co-receptors.[97] While the initial focus of studies was on direct endothelial stimulating activity of FGF1/2, multiple cell types respond to FGFs and their vascular roles may be both direct and indirect. Evidence suggests that FGF receptors signal an inductive pathway by upregulating VEGFR-2 in differentiating mesoderm before vascular morphogenesis. FGF2 may also induce neovascularization in adults directly or through activation of the VEGF–VEGFR pathway. Consequently, FGFs represent viable targets for vascular growth stimulation and inhibition, the latter including cancer.[97]

Inflammatory Mediators

Inflammatory and immune system responses not only impact the state of endothelial cells (above) but also vascular growth processes. For example, multiple cytokines produced in the tumor microenvironment stimulate (IL-4, IL-6, IL-17), or mitigate (IFNγ) various aspects of angiogenesis. These processes are also influenced by proangiogenic chemokines (IL-8/CXCL8, SDF-1/CXCL12), angiostatic chemokines (CXCL9, CXCL10, CXCL11), and other products of infiltrating or resident cells, as extensively reviewed in the recent literature.[86]

Coagulation Factors

Blood clotting and blood vessel growth processes are intimately interrelated through shared components of the hemostatic machinery, such as platelets, proteins of the coagulation system, and fibrinolysis. TF represents a multifunctional paradigm that illustrates integration between blood clotting, intracellular signaling, inflammation, and healing (see Chapter 125).[3,98]

TF/F3/CD142 is a member of the cytokine receptor superfamily and a single-pass transmembrane receptor for coagulation factor VII/VIIa (FVII/FVIIa). In addition to its cofactor role, TF complexes with other clotting factors and interacts with G-protein–coupled protease-activated receptors (PAR-1 and PAR-2), thereby triggering intracellular signals and alterations in gene expression.[99] Among the affected genes are proangiogenic chemokines (IL-8/CXCL8, CXCL1) and cytokines (VEGF).[100,101] TF knock-out mice exhibit abnormalities of their large vessels and microvasculature secondary to defects in mesenchymal and peri-endothelial cell function.[102] Elevated TF expression in various tumors and the associated angiogenic responses have been reported.[103] Expression of mutant oncogenes (K-*ras*, *EGFR*) or lost tumor suppressor genes (*PTEN*, *p53*) lead to increased TF expression and activity, and this may link tumor angiogenesis and the hypercoagulable states manifested in cancer.[103]

PAR receptors (PAR-1–4) and their agonists have also been implicated in blood vessel formation. Abnormal development of the vasculature occurs in 50% of mice that are deficient in FV. The affected mice die in utero, and the 50% embryonic lethality is similar to that observed in thrombin receptor (PAR-1)-deficient mice that die without obvious coagulation defects.[104] Thrombin can promote angiogenesis through a mechanism that is independent of fibrin formation. For example, thrombin can stimulate the release of angiogenic factors (e.g., VEGF-A) from tumor cells and platelets, as well as induce VEGFR-2 on endothelial cells.[105] In addition, mechanisms intersecting with thrombin activation and function, such as APC and its endothelial receptor (EPCR) have been shown to contribute not only to the regulation of hemostasis, but also to inflammation, cell proliferation, apoptosis, tumor progression, and angiogenesis.[99] APC increases proliferation of vascular endothelial cells and angiogenesis by activation of mitogen-activated protein kinase, phosphatidylinositol 3-kinase, and endothelial nitric oxide synthase (eNOS) pathways.[106]

Although clinical trials have suggested that treatment with low-molecular-weight heparins (LMWH) may improve the survival of cancer patients, these results require validation.[107] Many angiogenic growth factors (FGF, VEGF) contain heparin-binding motifs and heparanase-generated fragments of unfractionated heparin have anti-angiogenic effects in vitro. However, the mechanism responsible for the antitumor and antiangiogenic effects of these complex molecules needs to be defined.[108]

The potential involvement of fibrinolytic factors in angiogenesis has also been explored.[109] Plasminogen conversion to plasmin is regulated by several molecular mechanisms including tissue type (tPA) and urokinase (uPA) plasminogen activators and their inhibitors (PAI-1, -2, -3 and TAFIa). Pericellular proteolysis by plasmin changes the tissue microenvironment and promotes the invasion of cancer and endothelial cells, while cellular receptors for plasminogen and uPA (uPAR) interact with multiple signaling targets such as G-proteins and integrins, which may evoke cellular responses that can impact on blood vessel growth.[110]

Elements of the hemostatic system have also been implicated in such non-canonical processes as immunoregulation and cellular stemness. Examples of these linkages include changes in the expression of TF in stem versus non-stem brain tumor cell populations,[111] dependence of glioblastoma cell engraftment on PAR-1,[112] or elevated expression of platelet-activating protein, podoplanin (PDPN), in certain (albeit not all) tumor stem cell populations.[113] Strikingly, recruitment and retention of hematopoietic stem cells expressing EPCR have also been linked to PAR-1 signaling, further highlighting the emerging link between clotting factors, endothelial regulators, and cell fate.[114]

Extracellular Vesicles

Endothelial cells and other elements of the vessel wall, platelets, blood cells, and the various cells of the tissue microenvironment communicate not only through soluble factors but also by the exchange of complex (multimolecular) messages encapsulated in EVs. EV is an umbrella term comprising a spectrum of membrane-bound structures shed from cells through several mechanisms. For example, larger EVs (100 to 1000 nm in diameter) may directly bud from the plasma membrane as structures referred to as *microvesicles* (ectosomes or microparticles). In contrast, smaller EVs (30 to 150 nm in size), termed *exosomes*, originate within the cell, as secondary vesicles that are initially shed into the lumen of the late endosome-derived multivesicular body (MVBs). These small intraluminal vesicles (ILVs) are subsequently released from cells when MVBs contact the inner surface of the plasma membrane.[115] Other subsets of EVs include apoptotic bodies, large oncosomes, exosome-like membrane vesicles and several other structures generated through processes of membrane budding, membrane deformation associated with cell movement, cell fragmentation, and other processes. Different EV subsets carry distinct repertoires of bioactive and diagnostically important molecules including lipids, metabolites, proteins, nucleic acids (RNA, DNA), as well as, in some cases, also organelles, such as mitochondria.[115]

EVs protect and selectively transfer their molecular content between various “donor” and “recipient” cell populations within and outside of the vascular compartment. Platelets and RBCs are major sources of circulating EVs.[116] Other cellular subsets also contribute to the EV pool in plasma including endothelial, inflammatory and cancer cells. However, endothelial and myeloid cells are natural recipients of EVs shed to the circulation.[117] EVs (microparticles) play aforementioned important roles in hemostasis and thrombosis, in part as a source of phospholipids and as a mechanism transferring TF between cellular populations.[118]

Moreover, EVs may carry angiogenic growth factors (VEGF, FGF), inflammatory cytokines (IL-1), juxtacrine factors (ephrins, Dll4), enzymes (e.g., MMPs), extracellular matrix metalloproteinase inducer (EMMPRIN), and other bioactive cargo, including mRNA, microRNA, and DNA. Cancer-derived EVs contain active oncoproteins and oncogenic nucleic acids that may interact with and reprogram endothelial cells, stimulate their growth, trigger vascular permeability, and regulate angiogenesis.[66] Moreover, EVs are known to molecularly influence (educate) myeloid and stromal cells and platelets, thereby exerting wide-spread influences, including multiple facets of vascular growth processes.[66]

ENDOGENOUS INHIBITORS OF VASCULAR GROWTH

Multiple factors have been reported to negatively regulate vascular growth and morphogenesis.[1] Of interest is a class of endogenous angiogenesis inhibitors that originate as fragments of larger proteins that have little or no angiogenesis-related activity in their intact form. These include fragments of ECM proteins, such as fibronectin, collagen type IV α3 chain (tumstatin), and collagen type XIII (endostatin), as well as coagulation protein fragments such as cleaved plasminogen (angiostatin) and AT.[119] The mechanism of action of these molecules is poorly understood and depends on the properties of specific polypeptides, but the functional effect usually involves inhibition of endothelial proliferation or induction of apoptosis.

Other endogenous inhibitors include interferons, chemokines, interleukin-12 (IL-12), thrombospondin 1 (TSP-1), pigment epithelium-derived factor (PEDF), alternatively spliced isoforms of VEGF-A (VEGF-A_{xxx}b), soluble splice variant of VEGFR-1 (sVEGFR-1/sFLT-1) and several other entities.[2]

CELLULAR AND MOLECULAR PROGRAMS INVOLVED IN BLOOD VESSEL GROWTH AND HOMEOSTASIS

Angiogenesis stimulation and inhibition are but a small part of a complex vascular growth and remodeling machinery required for the formation, maintenance, and structural features of blood vessel networks as they respond to external and internal queues from embryogenesis to adulthood.

Prenatal Formation of the Vascular System

The human embryo develops the vascular system by the third week of gestation as a prerequisite for other organ systems and when its nutritional needs are no longer met by diffusion.[120] Vascular development proceeds in several phases. *Vasculogenesis* is the process whereby blood vessels form de novo through differentiation and self-assembly into a tubular structure of a subset of mesodermal precursors (hemangioblasts). The primary capillary plexus undergoes subsequent enlargement through *angiogenesis*, which as mentioned earlier, is the outgrowth of new capillaries from preexisting vascular channels, mainly due to physiological hypoxia. The resulting dense, but directionless initial vascular network undergoes pruning whereby some vessels regress, while others undergo enlargement, and become arteries or veins as a function of their position relative to the developing heart.[120,121] These processes involve vessel maturation whereby capillaries attract mural cell (pericyte) coverage and undergo remodeling through circumferential growth and vessel wall thickening. A similar process (arteriogenesis) is also operative during postnatal enlargement of preexisting collateral arterioles after occlusion of a supply artery.[120]

Postnatal Regulation of Vascular Growth

The vascular system is programmed to rapidly respond to changes in the microenvironment. Although these responses may be provoked by local factors (e.g., tissue injury or hypoxia), they are regulated at several levels, including locally, regionally, and systemically, and with the involvement of perivascular, vessel wall-associated, circulating, and BM-derived cells.[2] Cancer-related *neovascularization* exemplifies the diversity of processes that control cellular access to the perfused vascular space and illustrates the related terminology (Fig. 122.5). Indeed, an increase in vascular density or the presence of endothelial structures or blood within the tissue or tumor mass is not necessarily related to *angiogenesis* (see Fig. 122.4).[1] Instead, the vascular density and architecture represent a combination of parenchymal and vascular cell responses to metabolic demands and regulatory circuits operative in a given context. As mentioned earlier, these processes may include vasculogenesis-like recruitment of undifferentiated endothelial colony-forming cells (ECFC), formerly referred to as EPCs.[122] These cells are phenotypically similar to myeloid-derived, proangiogenic cells and may mediate vascular repair in response to endothelial damage (i.e., denudation) in larger vessels through several mechanisms.[122,123] Extravascular tissues may also actively increase their vascular access through processes of *vascular cooption* or *intussusception* whereby blood vessels may, respectively, become actively ensheathed or divided (split) by advancing external cellular masses.[124] Glomeruloid vessels, or *vascular tufting*, may also increase the proximity between the parenchyma and the vascular space through increased capillary looping directed by forces generated by pericytes.[125] The vascular wall may also undergo different forms of physiologic and pathologic *remodeling*, including circumferential lumen enlargement through growth, dilatation, or both. This is exemplified by capillary mother vessel formation prior to the onset of proper angiogenesis (see Fig. 122.5). The vascular wall thickening and diameter expansion, involving both endothelial and mural cells, and occurring during the formation of larger "feeding vessels" (or collaterals) upstream to tissue growth sites or ischemic regions, is often, as mentioned earlier, referred to as *arteriogenesis* or *arterio/venogenesis*.[126,127] Recruitment of pericytes to the newly assembled capillary endothelial tubes signifies the process of vascular maturation or stabilization.[2] Distinct mechanisms also regulate the programmed regression (*pruning*) of superfluous capillaries (e.g., during vascular *arborization*). Moreover, in cancer, new vascular structures are postulated to emerge as a consequence of the differentiation of cancer stem cells into endothelial-like or pericyte-like cellular populations (*vascular transdifferentiation*).[128,129] Cancer cells may also replace endothelial cells within the capillary walls of certain tumor types, giving rise to the aforementioned pseudo-endothelial lining (*vasculogenic mimicry*).[130] In the fibrotic liver, the porous endothelial lining of sinusoids is remodeled to resemble regular tight-walled capillaries (*capillarization*),[76] while conversely, the influence of VEGF and angiogenic growth factors in cancer leads to capillary *permeabilization* and leakiness.[131] Other (global) structural changes in the vessel wall or tree structure are simply referred to as *vascular remodeling*.[132] Each of these processes is driven by specialized cellular and molecular circuitry (program) and plays a unique role in vascular growth, homeostasis, and pathology, as outlined briefly in the following sections (see Fig. 122.5).[2,5,126,130]

Vasculogenesis

The existence and role of postnatal vasculogenesis are a subject of some debate. The process is thought to entail recruitment into sites of vascular growth, remodeling, and repair of cells with endothelial precursor (EPC)-like phenotype and properties resulting in their structural self-assembly, insertion into the vascular wall, or regulatory influence upon resident cells. These functions are now believed to reside in at least two BM-derived cellular populations, including the ECFCs, and myeloid-derived angiogenic cells (MACs).[122] While overt vasculogenesis occurs during early embryogenesis,[120] the role of this process during vessel growth in adults remains unclear and the structural contribution of BM-derived cells to pathological (tumor) vasculature is likely less than 5%.[133]

Angiogenesis

Postnatal angiogenesis represents the key mechanisms whereby new capillaries form under conditions of tissue growth, wound repair, inflammation, hypoxia, or proliferative disease (e.g., cancer). The new vascular structures emerge from preexisting endothelial channels mainly through a mechanism known as *sprouting angiogenesis* (see Fig. 122.4). In this case, the immediate triggering event usually involves the formation of a gradient of proangiogenic activity around hypoxic or activated cells. The resulting cascade of responses within the wall of the nearest capillary begins with local capillary distension to form an enlarged *mother vessel*. Although high concentrations of VEGF are sufficient to induce these changes,[131] the underlying molecular events usually involve a more global shift in levels of multiple angiogenesis inhibitors and stimulators ("angiogenic switch").[1] Some of these factors may upregulate VEGF in parenchymal, stromal, and inflammatory cells or act directly on the endothelium. Inflammatory cells often cluster at sites of angiogenesis prior to the formation of new blood vessels, where they contribute to the consolidation of the proangiogenic microenvironment or trigger vascular growth via VEGF-dependent and independent mechanisms.[2,5] Efficient sprouting involves metabolic reprogramming of endothelial cells, including the activation of glycolysis and upregulation of phosphofructokinase isoenzyme 3 (PFKFB3).[134]

Loss of anticoagulant surface by endothelium

Figure 122.5 PROCESSES OF VASCULAR GROWTH AND REMODELING IN PATHOLOGY. Neoplastic growths (also fibrosis or inflammation) can serve as paradigms for cellular programs regulating the proximity between parenchymal cells (including cancer cells) and the vascular lumen (see text for details). *Angiogenesis*, Recruitment of new capillary vessels through paracrine effects of angiogenic factors on endothelial cells of the preexisting vasculature; *Vasculogenesis*, recruitment of bone marrow-derived endothelial progenitor cells (EPCs) to the sites of vascular growth or repair (although EPC are essential during embryogenesis, postnatally their role is more limited as they lodge in, and contribute to, fragments of the newly formed vascular wall, or participate in the repair at sites of endothelial denudation); *Vasculogenic mimicry*, insertion and adaptation of non-endothelial cells into segments of the blood vessel lining; *Endothelial differentiation (or transdifferentiation) of cancer stem cells*, certain types of multipotential tumor-initiating (stem) cells may activate programs of endothelial or pericytic transdifferentiation and form segments of the newly formed vasculature; *Vascular (cancer) stem cell niche* is a site of proximity between endothelial cells and (cancer) stem cell populations, which receive paracrine (*angiocrine*) support and stimulation from endothelial cells; *Vessel permeabilization* occurs when the release of permeability factors (e.g., VEGF) from perivascular cells (e.g., cancer cells) leads to formation of endothelial cell fenestrae or other forms of trans- or para-endothelial permeability and leakage of plasma into the interstitium; *Arterio/venogenesis*, retrograde circumferential enlargement and remodeling of feeding vessels that supply expanding capillary networks with blood, a process involving bone marrow-derived myeloid cell recruitment through tissue-related stimuli and shear forces; *Pre-metastatic niche* is a modified local vascular and perivascular microenvironment, mostly through the exposure to cancer exosomes, prone to subsequent metastasis colonization in cancer; *Capillarization* is a change in the state of sinusoids resulting in their remodeling to capillary-like vessels, with the involvement of LECT2/TIE1 pathway; *Intussusception*, division of the vascular lumen into smaller tubes by ingrowth of external tissue pillars; *Glomeruloid vessel formation*, formation of bundles of vascular loops through forces (arrows) generated by endothelial, pericyte, and parenchymal cell interactions; *Vascular regression*, a process of regulated loss of endothelial viability, thrombosis, occlusion and collapse of a blood vessel; *Vascular cooption*, recruitment of cancer cells to the proximity of preexisting blood vessels; *Blood vessel invasion*, breaching of the blood vessel wall continuity by invading cancer cells; *Vascular thrombosis*, loss of patency, induction of intraluminal clotting as a result of changes in endothelial antithrombotic potential, physical damage, and loss of barrier function coupled with extravascular influence of highly coagulant cells (e.g., cancer cells).

Molecular Interplay Involved in Sprouting Angiogenesis

As mentioned earlier, VEGF plays a central and indispensable role in normal angiogenic sprouting. After exposure to this potent stimulator, ANG2 expression becomes upregulated in endothelial cells residing within the continuous monolayer of the capillary or mother vessel wall (phalanx cells). Endothelial ANG2 blocks tonic activation of the TIE2 receptor in the constitutive presence of ANG1, and by disrupting the key mechanism maintaining capillary structure leads to the detachment of pericytes. This is followed by local dissolution of the basement membrane (by MMPs), increase in vascular permeability, and extravasation of plasma proteins into the interstitium. The extravascular deposition of fibrin and the formation of a provisional ECM provide the scaffold for the formation of new capillaries.[2]

These processes liberate endothelial cells from physical constraints and initiate their directional migration in the form of a cellular column (angiogenic sprout) toward the source of the angiogenic stimulus (e.g., VEGF-expressing cells). Each sprout is composed of a single, specialized, leading endothelial cell (tip cell) equipped with hair-like, sensing projections (filopodia), which contain high concentrations of VEGFR2 and are rich in other regulators (e.g., PDGF-B, SDF-1, Apelin, and Dll4). In their gradient-seeking movement, tip cells are followed by a cohort of proliferating endothelial stalk cells, which express VEGFR1 and Notch. Stronger stimulation by VEGF results in VEGFR2-dependent upregulation of Dll4 in tip cells, allowing them to instruct their stalk cell counterparts (via Notch) to retain their phenotype, refrain from independent branching, and maintain VEGF signaling at lower levels. The latter is mediated, at least in part, by the upregulation of soluble VEGFR1, acting as a “VEGF sink.”

Exogenous blockade of the Dll4/Notch pathway leads to excessive generation of tip cells and sprouts (from stalk cells), resulting in the formation of an overly branched, hyperdense, nonperfused, and dysfunctional capillary networks (“nonproductive angiogenesis”).[135] Stimulation of Notch receptor by the Jagged 1 ligand modulates the effects of Dll4 on stalk cells and fine-tunes the capillary branching patterns.

The neighboring sprouts eventually anastomose to form new capillary loops. This process is mediated by interaction with myeloid cells expressing TIE-2 and NRP1 receptors.[27] Subsequent generation of the vascular lumen and resumption of blood flow occur through the formation of intercellular spaces between endothelial stalk cells.[2]

Vascular Maturation

To gain functionality, newly formed capillary loops must undergo maturation. This involves a buildup of a mural cell layer around the endothelial tube.[2] Responses of mural cells are triggered by secretion of PDGF-BB by endothelial tip cells, which attracts regional pericytes; a source of structural support and vessel-stabilizing, pro-survival ANG1 activity.[136] During these events, sphingosine 1 phosphate (S1P) regulates N-cadherin, which forms additional connections between endothelial cells and pericytes. Upon their attachment to the endothelial tube, pericytes assume a more mature phenotype under the influence of transforming growth factor beta 1 (TGFβ1).[136] Endothelial prolyl hydroxylase 2 (PHD2), an oxygen-sensing enzyme, also regulates pericyte recruitment. These mechanisms restore vascular integrity, mechanical resistance, endothelial cell survival, diminished dependence on VEGF, and restricted permeability.[2]

Capillarization

The formation of nonpermeable mature capillaries from permeable small sinusoid vessels (capillarization) may also accompany chronic pathology. For example, injured hepatocytes produce a mediator known as LECT2, which acts as a ligand for endothelial TIE1 receptor resulting in enhancement of TIE2 signaling, remodeling of sinusoids into capillaries, and progression of liver fibrosis.[76] It is possible that LECT2 and capillarization may also have roles in other contexts.

Lymphangiogenesis

The lymphatics comprise a low-flow, low-pressure system that collects extravasated fluid from the tissues and transfers it back to the venous system via the thoracic duct. Lymphatic vessels also serve an immune function by transporting lymphoid and antigen-presenting cells to lymphoid organs.[137,138] Lymphatic vessels share features with blood vessels, but they also exhibit differences such as the absence of basement membrane and filamentous attachment of endothelial cells to the surrounding tissue. While transcriptome of lymphatic endothelial cells exhibits 98% similarity to that of vascular endothelium, these cells also express distinctive markers (PROX1, VEGFR-3, LYVE-1, PDPN, CCL21), unique patterns of growth responses, and biological functions.[139]

Lymphatic network develops from venous endothelial cells that differentiate into lymphatic endothelium in response to specific molecular signals.[138] The branching and sprouting of lymphatics (lymphangiogenesis) resemble the process of angiogenesis. Lymphangiogenesis is triggered by VEGF-C and VEGF-D, both activating VEGFR-3 and also depend on the activity of ANG2 which, unlike in blood vessel capillaries, acts as a TIE2 agonist in lymphatic endothelium.[138] The α9β1 integrin and matrix interacting protein CCBE1 are necessary for proper lymphatic development, and the homeobox transcription factor PROX1 controls the program of lymphatic endothelial cell differentiation. Another regulator of early lymphatic endothelial cell specification is SOX18 (sex-determining Region Y Box 18), a transcriptional regulator of PROX1expression.[140]

Lymphatics play important roles in pathology. For example, they are the main conduits of lymphatic metastasis in cancer. Whether lymphatic vessel density in human tumors correlates with disease progression is not clear, but in animal models, induction of lymphangiogenesis and lymphatic dilation by VEGF-C or VEGF-D promotes lymph node metastasis.[137] Dysfunction of lymphatics in lymphedema can be caused by congenital defects, parasitic (filariasis) or neoplastic obstruction, or surgical resection causing retention of interstitial fluid in the tissue lacking functional drainage. Congenital lymphedema (Milroy disease) is linked to inactivating mutations of VEGFR-3.[138]

Vasculogenic Mimicry

Insertion of cancer cells into endothelial lining associated with change in their phenotype (vasculogenic mimicry), or a process of overt transdifferentiation of cancer stem cells to vascular-like cellular populations exemplify a possible involvement of non-endothelial lineages in the formation of vascular channels.[129] Vasculogenic mimicry occurs during normal placentation and in tumors, such as melanoma, or mouse teratoma. During these events, non-endothelial cells may adopt some of the morphologic and antigenic attributes of proper endothelium.[130] In human glioblastoma, cancer stem cells were reported to undergo endothelial or pericyte transdifferentiation, including the expression of corresponding lineage markers and some contribution to the vascular wall and perivascular invasion. The scope and functional role of these processes in human disease remain unclear and controversial.[128]

Vascular Cooption

Cancer cells may actively adopt a growth and invasion pattern around preexisting blood vessels.[124] This process (vascular cooption) is observed in highly vascularized organs, such as the lungs, liver, and brain, resulting in a nonangiogenic form of tumor access to blood vessel networks and resistance to antiangiogenic agents. Coopted vessels may undergo secondary structural alterations, which may result in their remodeling, formation of occlusive thrombi, and regression that can lead to ischemia.[124] The extent of the vessel cooption process in cancer can be considerably greater than previously thought and appears to be controlled by both the properties of the vasculature and the phenotype of cancer cells.[124]

Vascular Remodeling, Regression, and Endothelial Apoptosis in the Course of Vascular Growth

Even though the vasculature is laid down before circulation begins, hemodynamic forces are important for its maintenance and remodeling. Most of the vessels formed during vasculogenesis regress or are remodeled. A chronic decrease in blood flow results in narrowing of the vessel lumen. Remodeling, which involves loss of some vessels (pruning), as well as changes in lumen diameter and wall thickness, requires both cell death and proliferation (as well as remodeling of the ECM).[141] In addition to survival signals transmitted by integrins and growth factors also shear stress and mechano-signaling are important for endothelial survival and vessel healing after injury, as described in previous sections. While endothelial cells are exquisitely sensitive to death from detachment (anoikis), they also express several anti-apoptotic molecules to maintain viability when quiescent and when stressed or involved in vascular growth processes to maintain the intricate balance between their survival or elimination.[142]

Arteriogenesis

As mentioned earlier, this term refers to upstream circumferential enlargement of supply vessels that drain into a particular vascular bed, a process often triggered by the occlusion of the main supply vessel, or by expansion of the capillary volume (e.g. in cancer).[126] In adulthood, arteriogenesis is responsible for the formation of collateral arterial circulation to bypass pathological obstruction of arterial blood supply to tissues.[143] Remodeling of a preexisting collateral small arteriole is thought to be caused by flow-induced changes secondary to occlusion of the supply artery. The consequent increase in shear stress of blood forced through the collateral arteriole activates endothelial cells, resulting in myeloid cell (monocyte) recruitment and their infiltration into the media. Elaboration of various cytokines, growth factors, and proteases from monocytes and endothelial cells causes matrix degradation, smooth muscle cell proliferation, and rapid enlargement of the preexisting arteriole. Factors thought to promote arteriogenesis include FGF-2, PlGF, PDGF-BB, TGFβ1, monocyte chemoattractant protein 1 (MIP-1), and GM-CSF.[144]

MECHANISMS TRIGGERING BLOOD VESSEL GROWTH

Angiogenesis represents the predominant form of postnatal vascular growth and a paradigm of blood vessel responses to external cues. Cessation of physiological quiescence of endothelial cells and the angiogenic switch may occur in response to hypoxia, metabolic stress, growth factors, inflammatory mediators, or after activation of the coagulation system or changes in the secretome of adjacent cells that have undergone malignant transformation. These mechanisms are interdependent and often converge upon the regulation of the VEGF gene[2] but may also involve additional (or alternative) complex networks of molecular effectors. Although angiogenic responses may be morphologically similar, they exhibit highly context-dependent traits.[145]

The most studied network in this regard is the regulation of VEGF by the hypoxia response pathway. In this setting, VEGF transcription is controlled by dimeric hypoxia-inducible factors 1 and 2 (HIFs). Normally, the HIF1 alpha subunit (HIF-1α) is constitutively degraded by oxygen-dependent prolyl- and aspargyl hydroxylases, von Hippel–Lindau (VHL) ubiquitin ligase, and the proteasome.[146] Hypoxia blocks this process, resulting in elevated HIF activity and VEGF production by parenchymal, stromal, and inflammatory cells. Several other mechanisms of proangiogenic responses driven by hypoxia have also been described (e.g., NFκB, EGR1).[146]

In addition, exposure of cells to growth factors (EGF, FGF, HGF) and inflammatory cytokines (IL-6) may upregulate VEGF, and some of these effectors may also directly stimulate endothelial cells.[2] Activation of oncogenes (e.g., RAS) and loss of tumor suppressors (VHL) may lead to upregulation of VEGF and often pleiotropically affect other angiogenic growth factors in cancer cells, even under conditions of normoxia.[147] Oncogenic transformation also shuts down some of the angiogenic inhibitors, contributes to coagulopathy (through upregulation of TF and thrombin receptors), and enhances proangiogenic cellular vesiculation (biogenesis and emission of EVs loaded with vascular mediators). Indeed, oncogenic pathways often mimic, distort, or exacerbate the effects of hypoxia, inflammation, or microenvironmental stress.[147]

THERAPEUTIC IMPLICATIONS OF ENDOTHELIAL AND ANGIOGENIC RESPONSES TO DISEASE

Vascular events associated with cancer, hemangioma, viral infections, or vascular malformations have the potential to trigger hematologic consequences, either spontaneously or during therapeutic angiogenesis or antiangiogenesis. These linkages are still poorly understood but often include one or more of the following processes: (1) endothelial cell activation associated with intravascular upregulation of TF, adhesion molecules, and other mediators; (2) disruption of vascular wall continuity; (3) recruitment of inflammatory cells; (4) increased vascular permeability with resultant extravasation and activation of circulating coagulation factors; (5) platelet activation; (6) contact of procoagulant cell surfaces (e.g., metastatic cancer cells) with circulating blood; (7) flow perturbations and stasis; (8) indirect external effects (e.g., indwelling catheters or administration of chemotherapy); and (9) shedding of procoagulant, anticoagulant, or bioactive EVs (microparticles), and soluble factors into blood. In addition, blood vessel-directed therapies and their capacity to modulate or exacerbate some of these events represent an emerging challenge in hematology (see Chapters 94 and 151).

Revascularization Therapy

Ischemic heart muscle, peripheral artery disease, non-healing burns, and other causes of tissue hypoperfusion may benefit from controlled induction of angiogenesis or collateral circulation. Ongoing efforts are exploring the utility of recombinant growth factors (FGF, VEGF), gene therapy vectors, or cell therapy approaches (including mesenchymal stem cells) in inducing effective revascularization of affected tissues, as reviewed elsewhere.[148,149]

Antiangiogenic Therapy

The term “antiangiogenesis” is often used incorrectly to describe inhibition of all types of pathological vascular growth in diverse disease states collectively referred to as angiogenesis-dependent diseases.[1] While the nature of the vascular pathology in some of these conditions is not tantamount to angiogenesis, they all exhibit destructive endothelial cell responses that may be pharmacologically targetable. Examples of such diseases include neovascular age-related macular degeneration (NVAMD), retinopathy of prematurity (ROP), diabetic retinopathy (DR), vascular malformations, psoriasis, Kaposi sarcoma, cavernous hemangioma, arthritis endometriosis, and several forms of cancer.[1]

TUMOR ANGIOGENESIS AND ANTIANGIOGENESIS

The disorganized signaling cues during tumor angiogenesis may produce highly abnormal, leaky, tortuous, prothrombotic, and poorly perfused vasculature (vessel “abnormalization”), which may contribute to aberrant hemostasis.[2] Antiangiogenic agents may cause further perturbation by selective destruction of tumor-associated endothelial cells or by inhibition of their stimulatory circuitry.[1] Several classes of antiangiogenic compounds have been evaluated to date, including derivatives of natural angiogenesis inhibitors (e.g., endostatin or tumstatin), inhibitors of proangiogenic signaling pathways (antibodies, small-molecule agents), and agents that block proangiogenic inflammatory pathways (e.g., thalidomide analogs). Anticancer drugs may also be administered in low but frequent doses (metronomic chemotherapy) to target endothelial, immune, and regulatory cells preferentially.[1,4,150]

Bevacizumab (Avastin), a humanized monoclonal anti-VEGF antibody, was the first antiangiogenic agent to be approved (in 2004) for cancer treatment, and the drug is now used to treat colorectal, lung, kidney, recurrent brain tumors, and other cancers.[150] Another neutralizing antibody directed against VEGFR2 (Ramucirumab) has subsequently been introduced into oncology practice[151] along with anti-VEGF receptor-antibody chimeric inhibitor (Aflibercept). Several tyrosine kinase inhibitors (TKIs) with anti-VEGFR or multikinase activity (sunitinib, sorafenib, pazopanib, axitinib, regorafenib, nintedanib, lenvatinib, cabozantinib) are also in common use. Antiangiogenic activity was also documented in the case of inhibitors blocking oncogenic pathways that drive the VEGF production by cancer cells.[147] These agents include agents blocking signals generated by epidermal growth factor receptor (EGFR) and HER2 (cetuximab and trastuzumab, respectively), along with inhibitors of other oncogenic proteins.[147]

VEGF/VEGFR antagonists are mostly used in combination with chemotherapy, suggesting that they may serve as chemosensitizers, mediators of vascular normalization and immunomodulators.[2] Studies are underway to develop drugs that specifically target pathologic angiogenesis while sparing natural blood vessel growth (e.g., blockers of PlGF), or agents targeting pre-established tumor blood vessels (e.g., vascular disrupting agents [VDAs]).[4,150]

The overall objectives of antiangiogenic therapy in cancer are at least threefold: (1) to induce tumor hypovascularity, thereby causing hypoxic damage to cancer cells; (2) to deprive cancer (stem) cells of the paracrine growth stimulation and support rendered by angiogenic endothelial cells (anti-angiocrine effect)[147,152]; and (3) at lower doses, to induce vessel "normalization," resulting in the improved tumor perfusion associated with increased sensitivity to chemotherapy, radiation, and immunotherapy.[2] In experimental settings, promotion of blood vessel growth/dilatation combined with chemotherapy may exert an anticancer effect, and it is possible that rational and context-dependent modulation of the tumor vasculature may eventually replace global approaches of anti-angiogenesis.[153]

ANGIOGENESIS AND ANTIANGIOGENESIS IN HEMATOPOIETIC MALIGNANCIES

The vascular BM stroma plays a pivotal role in leukemogenesis.[154] Indeed, angiogenesis, increased vascular density, and increased levels of angiogenic growth factors have all been observed in the BM of patients with hematopoietic malignancies. VEGF may play multiple roles in this context, including as (1) a vascular growth stimulator; (2) a paracrine growth factor for leukemic stem cells[154]; and (3) an inducer of angiocrine interactions between these cells and the endothelial niche. Consequently, a wide spectrum of antiangiogenic agents, including VEGF antagonists (bevacizumab, sorafenib, sunitinib, cediranib), have been investigated as candidates for the treatment of hematologic disorders, such as acute myelogenous leukemia, chronic myelogenous leukemia, acute lymphoblastic leukemia, myelodysplastic syndrome, non-Hodgkin lymphoma, multiple myeloma, and others. Additional agents with antiangiogenic activity have also been explored, including bortezomib and anti-inflammatory antiangiogenics (thalidomide and lenalidomide).[154] While some of the latter agents are already in human use in hematologic malignancies (e.g., in mantle cell lymphoma, multiple myeloma, and myelodysplastic syndrome), the contribution of antiangiogenic effects to therapeutic efficacy is not clear.

HEMATOLOGIC COMPLICATIONS ASSOCIATED WITH BLOOD VESSEL-DIRECTED AGENTS

Manipulation of endothelial and mural cells during pro- and antiangiogenic therapy creates the potential for side effects.[155,156] The most extensive clinical experience in this regard is in cancer, where some toxicities (e.g., hypertension, proteinuria, fatigue, hypothyroidism) have been frequently observed, along with hematologic side effects such as thrombosis and/or bleeding. While cancer patients are prone to thrombosis,[157] antiangiogenic therapy increases the risk of venous thromboembolism or arterial thrombosis.[6] The risk varies depending on the agent and the type of cancer and is exacerbated by accompanying chemotherapy or hormonal therapy.[157] Thrombosis is of particular concern in patients with multiple myeloma who receive thalidomide derivatives in combination with anthracyclines and dexamethasone. In this case, the risk of thrombosis may be as high as 75%.[157] Bevacizumab may increase the risk of arterial thrombosis up to two-fold in patients with solid tumors, especially in the elderly with comorbid conditions. However, these estimates are variable (0.9% to 19.4% according to different studies) and drug-specific, because small-molecule TKIs acting on VEGFR are less likely to trigger venous thromboembolism (0% to 3%).[157]

Bleeding complications have also been recorded with several of these agents, ranging from minor to life threatening.[158] In general, however, antiangiogenic agents are relatively well tolerated, and their side effects are usually manageable with careful monitoring and standard supportive care.[6]

RELATIONSHIP BETWEEN THE VASCULATURE AND HEMATOPOIESIS

Hematopoietic cells and endothelial cells are intertwined in several ways. First, there is the likely existence of a common precursor, the hemangioblast, in the yolk sac (see *vasculogenesis*). Second, definitive hematopoietic stem cells emerge from specialized endothelial cells during embryogenesis in a process called endothelial-to-hematopoietic transition (see Chapter 9). Third, the endothelium is intimately involved in adult hematopoiesis, having a supportive role structurally and nutritionally (see also the section on BM Sinuses). Fourth, BM-derived myeloid cells play crucial regulatory roles in angiogenesis, arteriogenesis, and other processes of vascular growth and remodeling (see section on Cellular and Molecular Pathways Involved in Blood Vessel Formation). Finally, the endothelium organizes the controlled egress and ingress of hematopoietic cells in hematopoietic and other tissues (see Interaction of Blood Cells With the Vessel Wall).[159]

Between embryonic day 9.5 and 11.5 in the mouse and 4 to 6 weeks of gestation in the human, hemogenic endothelial cells undergo transdifferentiation to hematopoietic stem and progenitor cells.[160,161] This process of endothelial-to-hematopoietic transition occurs mainly in the ventral aspect of the dorsal aorta of the aorta-gonadal-mesonephros region, but also in other large arteries. Hemogenic endothelial cells express transcriptomes that are distinct from the surrounding vascular endothelial cells, and during embryogenesis, clusters of hematopoietic cells are observed to emerge from these cells. Hematopoietic stem cells thus generated then migrate to the fetal liver. Hemogenic endothelial cells initially express VE-cadherin, indicative of their endothelial origin, and sequentially upregulate the hematopoietic markers CD41, c-Kit, CD43, and CD45 during their transition to hematopoietic stem and progenitor cells. Runx1 is a critical transcription factor that identifies hemogenic endothelium and is required for their hematopoietic transdifferentiation. Additional key transcription factors driving this process include Spi1, Gfi1, FosB, and others.[162]

Mounting evidence indicates that hematopoietic stem and progenitor cells are not randomly distributed in the BM, but rather are spatially associated with blood vessels, the vascular niche. Endothelial cells, through paracrine and juxtacrine activity, in concert with other stromal and hematopoietic cells, provide a finely tuned system to modulate hematopoiesis in the BM such that differentiation, proliferation, migration, and self-renewal occur in a regulated fashion at steady state and in response to stress and injury.[30,163,164] Although there is minimal functional evidence in humans, several lines of evidence suggest that the human hematopoietic stem cell niche is like that in the mouse.[165] The physical proximity of endothelium and hematopoietic precursors within the marrow and the requirement of blood cells to transit through marrow endothelium to reach the circulation suggests an important role for endothelium. Both yolk sac and marrow endothelial cells support long-term proliferation and differentiation of hematopoietic cells in vitro. In addition to the expression of chemokines (CXCL12) and adhesion molecules (E-selectin, VCAM-1) (see also the section on BM Sinuses), marrow endothelial cells constitutively express high levels of IL-6, stem cell factor, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF).[30] Like normal hematopoietic stem cells, leukemic stem cells dynamically interact with the BM stroma and vasculature, often in the context of increased angiogenic responses.[164]

Human endothelial cells express receptors for IL-3, stem cell factor, erythropoietin, and thrombopoietin, and show functional responses to IL-3 and erythropoietin. The shared responses to growth factors, combined with the importance of macrophages in angiogenesis and the production of cytokines by monocytes and macrophages, suggest that hematopoietic cells play a reciprocal role in maintaining the endothelium.

SUMMARY

The functional integration of the vascular system, BM, and circulating blood results in a high degree of biologic interdependence in health and disease. While this may not always be clinically obvious, the existence of these subtle links necessitates a greater consideration of blood vessel-regulating processes in the pathogenesis and therapy of hematologic disorders.

CHAPTER 123

MEGAKARYOCYTE AND PLATELET STRUCTURE

Kellie R. Machlus and Joseph E. Italiano, Jr.

Platelets are small anucleate fragments that are formed from the cytoplasm of megakaryocytes and have a characteristic discoid shape. To assemble and release platelets, megakaryocytes become polyploid by endomitosis and follow a maturation program that results in the conversion of the bulk of their cytoplasm into multiple long processes called *proplatelets*. To produce its quota of 1000 to 2000 platelets, a megakaryocyte may release as many as 10 to 20 proplatelets. Platelets then form selectively at the ends of proplatelets. As platelets develop, their content of granules and organelles is delivered to them in a stream of individual particles moving from the megakaryocyte cell body to the nascent platelet buds at the proplatelet tips. Platelet formation can be arbitrarily divided into two phases. The first phase of megakaryocyte differentiation and maturation takes days to complete and requires megakaryocyte-specific growth factors such as thrombopoietin (TPO). Massive nuclear proliferation without cell division (endomitosis) to 16 to 32 N and enlargement of the megakaryocyte cytoplasm occur because the megakaryocyte is filled with cytoskeletal proteins, platelet-specific granules, and sufficient membrane to complete the platelet assembly process. The second phase is relatively rapid and can be completed in hours. During this phase, megakaryocytes generate platelets by remodeling their cytoplasm first into proplatelets, then preplatelets, which are released into the circulation, where they undergo repeated fission to generate discoid platelets.

MEGAKARYOCYTE DEVELOPMENT

Endomitosis

Hematopoietic stem cells, which are endowed with the genetic capacity to differentiate into all blood cell lineages, are induced down the pathway to become megakaryocytes by their exposure to growth factors such as TPO.[1] Megakaryocytes become polyploid (i.e., 4 N, 16 N, 32 N, 64 N) through repeated cycles of deoxyribonucleic acid (DNA) replication without cell division.[2–5] Normal ploidy ranges from 4 to 64 times the haploid DNA complement, but the majority of cells fall within three ploidy classes (8 N, 16 N, and 32 N), with 16 N being dominant (Fig. 123.1).[6,7] Ploidy number appears to be a predetermined event, possibly signifying genetic diversity among megakaryocyte populations. Megakaryocyte polyploidization results in a functional gene amplification whose likely function is an increase in protein synthesis.[8] This process, called *endomitosis*, is a shortened mitosis caused by a block in late anaphase, thereby bypassing cytokinesis.[9,10]

Cells undergoing diploid mitoses proceed through cytokinesis and complete abscission division, whereas megakaryocytes exhibit regression of the cleavage furrow and reenter G_1 as polyploid cells.[1] During polyploidization of megakaryocytes, the nuclear envelope breaks down, and an abnormal spherical mitotic spindle forms. The spindle has attached chromosomes that align from a position equidistant from the spindle poles. Sister chromatids segregate and move toward their respective poles (anaphase A). However, the spindle poles fail to move apart and do not undergo the microtubule-driven separation typically observed during anaphase B. Individual chromatids are not moved to the poles, and subsequently a single nuclear envelope encapsulates the entire set of sister chromatids.[9,10] In most cell types, checkpoints and feedback controls ensure that DNA replication and cell division are tightly coupled. Megakaryocytes appear to be an exception to this rule, indicating they have managed to deregulate this process. Proposed mechanisms for regulating endomitosis include a reduction in mitosis-promoting factor[11,12] or decreased expression of cyclin B.[12–15] Cyclins appear to play a critical role in directing endomitosis. Cyclin D3 is overexpressed in the G_1 phase of maturing megakaryocytes,[16] but triple knockout of cyclins D1, D2, and D3 in mice does not appear to affect megakaryocyte development.[17] In contrast, cyclin E–deficient mice exhibit a profound defect in megakaryocyte development.[18] The molecular programming involved in endomitosis is characterized by the mislocalization or absence of at least two critical regulators of mitosis: the chromosomal passenger proteins Aurora-B/AIM-1 and Survivin. AIM-1 (absent in melanoma 1), a serine/threonine kinase in the Aurora family that is implicated in mitosis, is downregulated as megakaryocyte polyploidization occurs, suggesting its loss may lead to the abortive mitosis and polyploidization.[19,20] However, while Aurora kinase A is required for hematopoiesis, it is dispensable for mouse megakaryocyte endomitosis and differentiation.[21] Whereas deletion of the anaphase promoting complex (APC)/C cofactor Cdc20 causes mitotic arrest and severe thrombocytopenia, lack of the kinases Aurora-B, Cdk1, or Cdk2 does not affect endomitosis of megakaryocytes or platelet counts. Deletion of Cdk1 forces a change to endocycles without mitosis, whereas polyploidization in the absence of cdk1 and cdk2 occurs in the presence of aberrant replication events. Notably, ablation of these kinases rescues defects in Cdc20-null megakaryocytes. These observations suggest that endomitosis can be functionally replaced by alternative polyploidization mechanisms in vivo. One explanation for endomitosis could be inhibition of microtubule-based forces in anaphase B. Spindle pole separation during anaphase B is thought to be powered by the sliding of antiparallel interdigitating microtubules past each other[22] mediated by the mitotic kinesin-like protein 1. This protein localizes at regions of overlapping microtubules during anaphase B, and studies in vitro indicate that it can slide microtubules past each other.[23] Therefore lack of spindle pole separation during endomitosis may result from failure of megakaryocytes to undergo normal spindle orientation and/or the absence of signals that localize or activate a kinesin motor molecule that provides force for sliding.

Cytoplasmic Maturation

Megakaryocytes, the largest of the hematopoietic cells, undergo a pronounced cytoplasmic maturation to attain their large volumes. Cytoplasmic maturation begins during endomitosis and increases considerably after all DNA amplification has ended (Fig. 123.2). Megakaryocytes enlarge dramatically as they mature, reaching sizes of 100 to 150 µm in diameter in culture and in bone marrow. During this process, the megakaryocyte cytoplasm rapidly fills with platelet-specific proteins, organelles, and membrane systems that ultimately are subdivided and packaged into platelets (Fig. 123.3). Their cytoplasmic space expands and, except for the most cortical regions, becomes densely filled with internal membranes that subsequently serve as the repository for the plasma membrane to be regurgitated for coating proplatelets as they extend.[24] This internal membrane system, which is one of the most striking features of mature megakaryocytes, has been referred to as the *demarcation membrane system* (DMS) or, more recently, the invaginated membrane system (IMS). The DMS, first described by Yamada in 1957, consists of an extensive, tortuous, branching network of membrane channels composed of flattened

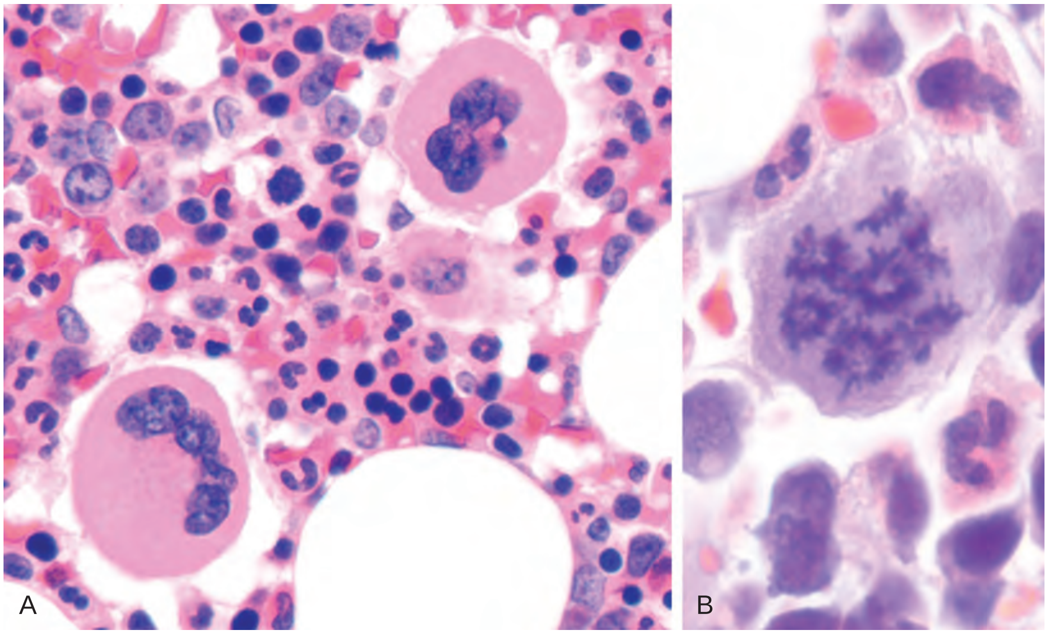

Figure 123.1 POLYPLOID MEGAKARYOCYTES IN THE BONE MARROW. Large polyploid megakaryocytes are seen in the bone marrow on a typical hematoxylin and eosin–stained slide and are recognized by their abundant pink cytoplasm and large nuclei (A). The degree of polyploidization is difficult to determine. Rarely, megakaryocytes can be seen in mitosis (B), and when chromosomes are aligned in metaphase plates, the high ploidy level become quite apparent. In the mitotic figure illustrated, the megakaryocyte is a 16 N form with eight 2 N metaphase plates.

Figure 123.2 SUMMARY OF THE MAJOR EVENTS THAT LEAD TO PLATELET FORMATION AND RELEASE FROM MEGAKARYOCYTES. Hematopoietic stem cells are converted into megakaryocytes by exposure to the specific growth factor thrombopoietin (TPO). TPO initiates a maturation program that amplifies the megakaryocyte DNA and leads to synthesis of platelet-specific proteins. In particular, cytoskeletal elements, membrane systems, and receptor proteins are made in bulk, and the megakaryocyte becomes filled with platelet-specific granules. Platelet production begins when microtubules aggregate in the cell cortex, and one pole of the megakaryocyte spontaneously elaborates pseudopodia. These begin as large blunt pseudopodia, which subsequently thin and branch into proplatelets. The branching reaction is dependent on a localized assembly of actin and is inhibited by drugs that disrupt actin filaments. Platelets are assembled primarily at the ends of the proplatelets. Intracellular organelles are delivered to the platelet buds along microtubule tracks in the shafts. Platelets are released from the ends of proplatelets. *FOG*, Friend of *GATA1*; *GATA1*, GATA-binding protein 1.

cisternae and tubules. Initially, the DMS was proposed to play an essential role in platelet formation by defining preformed “platelet territories” or “platelet fields” within the megakaryocyte cytoplasm.[25,26] Release of individual platelets was postulated to occur by massive fragmentation of the megakaryocyte cytoplasm along DMS fracture lines between these fields. However, studies demonstrating that platelets are primarily assembled and released from proplatelet ends (see Platelet Formation later in this chapter) are inconsistent with this notion and indicate instead that the DMS functions predominantly as a membrane reserve for proplatelet formation.[24] Direct visualization of mature DMSs containing phosphatidylinositol 4,5-bisphosphate suggests that it is the source of proplatelet membranes.[2] Studies by Eckly et al.[27] have begun to provide insights into how the DMS forms and matures. To develop the DMS, the megakaryocyte

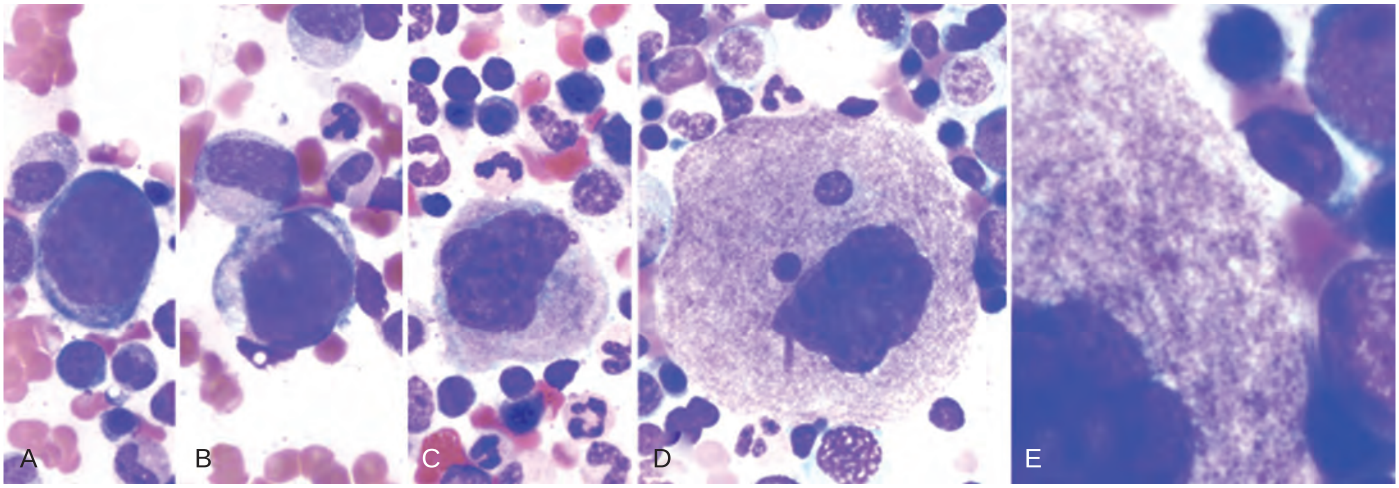

Figure 123.3 PLATELET PRODUCTION IN THE MEGAKARYOCYTE. (A) Immature polyploid megakaryoblast with little differentiation. (B) Megakaryocyte with early Golgi zone. (C) Early platelet production in cytoplasm. (D) Late-stage megakaryocyte with abundant internal membranes, organelles, and platelet-specific proteins. (E) Early formation of demarcation membranes.

plasma membrane enfolds at specific sites to generate a perinuclear pre-DMS. Next, the pre-DMS is expanded into its mature form by material added from Golgi-derived vesicles and by endoplasmic reticulum–mediated lipid transfer. This structural description is in line with studies on platelet glycosyltransferases, which arrive early in the forming DMS and eventually make their way to the megakaryocyte and platelet surface.[28] Thus far, only a handful of proteins that participate in DMS formation have been identified based on alteration in DMS structure in certain knockout mouse models. Membrane-deforming proteins that use F-BAR (Family of Bin-Amphysin-Rvs) domains to curve membranes or use guanosine triphosphate (GTP) as an energy source to bud vesicles from membranes appear to be necessary for normal megakaryocyte maturation and platelet release. Gross disruptions in DMS structure are found in megakaryocytes isolated from either filamin A–knockout, pascin2-knockout, dynamin 2–knockout, or Cdc42-interacting protein 4 (CIP4)-knockout mice. CIP4 is an F-BAR protein that induces membrane tubulation and localizes to membrane lipids via its BAR domain and interacts with the Wiskott-Aldrich syndrome protein (WASp).[29] CIP4$^{-/-}$ mice have mild thrombocytopenia, with a 25% decrease in the platelet count. While megakaryocyte numbers and ploidy are normal in CIP4$^{-/-}$ knockout mice, megakaryocytes isolated from these mice are less effective in producing proplatelets in vitro.

Dynamins are highly conserved, large mechanochemical GTPases involved in endocytosis and vesicle transport, and mutations in dynamin 2 have been associated with thrombocytopenia in humans. Dynamin 2–dependent endocytosis is required for megakaryocyte development in mice.[30] Filamin connects glycoprotein (GP)Ibα to the actin cytoskeleton and binds pacsin2, a molecule that deforms membranes. Pacsin2 has an F-BAR and SH3 domain that binds dynamin and N-WASp. Pacsin2 plays an important role in organizing internal membranes during megakaryocyte development and platelet production.

Maturing megakaryocytes, like other granulated cells, contain an abundance of ribosomes and rough endoplasmic reticulum, where protein synthesis occurs. During this phase of megakaryocyte development, the cytoplasm fills with cytoskeletal proteins, platelet-specific receptors and secretory granules, and normal cellular organelles such as mitochondria and lysosomes. A hallmark of mature megakaryocytes is their abundance of platelet-specific secretory granules. The two specific granules destined for platelets are α-granules and dense granules. α-Granules, the more abundant (approximately 40 to 80 per platelet) and larger of the two (200 to 500 nm in diameter), contain proteins that enhance platelet adhesion, promote cell-cell interactions, regulate angiogenesis, and stimulate vascular repair. α-Granules store matrix proteins and contain GP receptors in their membranes (Fig. 123.4A). The bulk of cellular P-selectin and a portion of $\alpha_{IIb}\beta_3$ and the GPIb/IX/V complex, a receptor for von Willebrand factor (vWF), are expressed in the membranes of α-granules. Adhesion molecules within the granules include, but are not limited to, vWF, fibrinogen, fibronectin, vitronectin, and thrombospondin. α-Granule proteins can be derived from different sources. Some proteins, such as α-thromboglobulin and vWF, are synthesized by megakaryocytes. However, fibrinogen, also a major component of α-granules, is not synthesized by megakaryocytes and is instead taken up from plasma by an endocytic mechanism requiring fibrinogen binding to $\alpha_{IIb}\beta_3$. Although little is known about the intracellular trafficking of proteins in megakaryocytes, experiments using cryosectioning and immunoelectron microscopy suggest that multivesicular bodies are an essential intermediate stage in the formation of platelet α-granules. During megakaryocyte development, large (≈0.5 μm) multivesicular bodies undergo a gradual transition from granules containing 30 to 70 nm internal vesicles to granules containing secretion concentrates.

The second and smaller type of platelet granule is the dense granule. Platelets contain relatively few dense granules (approximately 4 to 6 per platelet), which are approximately 150 nm in diameter. Dense granules have electron opaque cores, which give them a bull's-eye appearance, and function primarily to recruit additional platelets to sites of vascular injury. Dense granules contain soluble activating agents, such as serotonin and adenosine diphosphate (ADP), as well as divalent cations. A novel electron-dense tubular system–related compartment called the T-granule has been described in platelets. The T-granules contain Toll-like receptor 9 (TLR9), which links the innate and adaptive immune response during infectious inflammation. TLR9 colocalizes with protein disulfide isomerase, a vascular thiol isomerase, and is associated with either vesicle-associated membrane protein (VAMP) 7 or VAMP 8. T-granules are believed to be a remnant of the endoplasmic reticulum and are derived from the dense tubular system.[31]

When the megakaryocyte reaches a certain point of maturation, proplatelet production begins, and granules are sent into the proplatelets, destined for platelets.

REGULATION OF MEGAKARYOCYTE DEVELOPMENT

The development of megakaryocytes and the process of platelet biogenesis occur within a complex bone marrow environment where both cytokines and adhesive interactions play an essential role. Megakaryocytes are imprisoned within the subendothelial layer of the bone marrow sinuses, where development and platelet

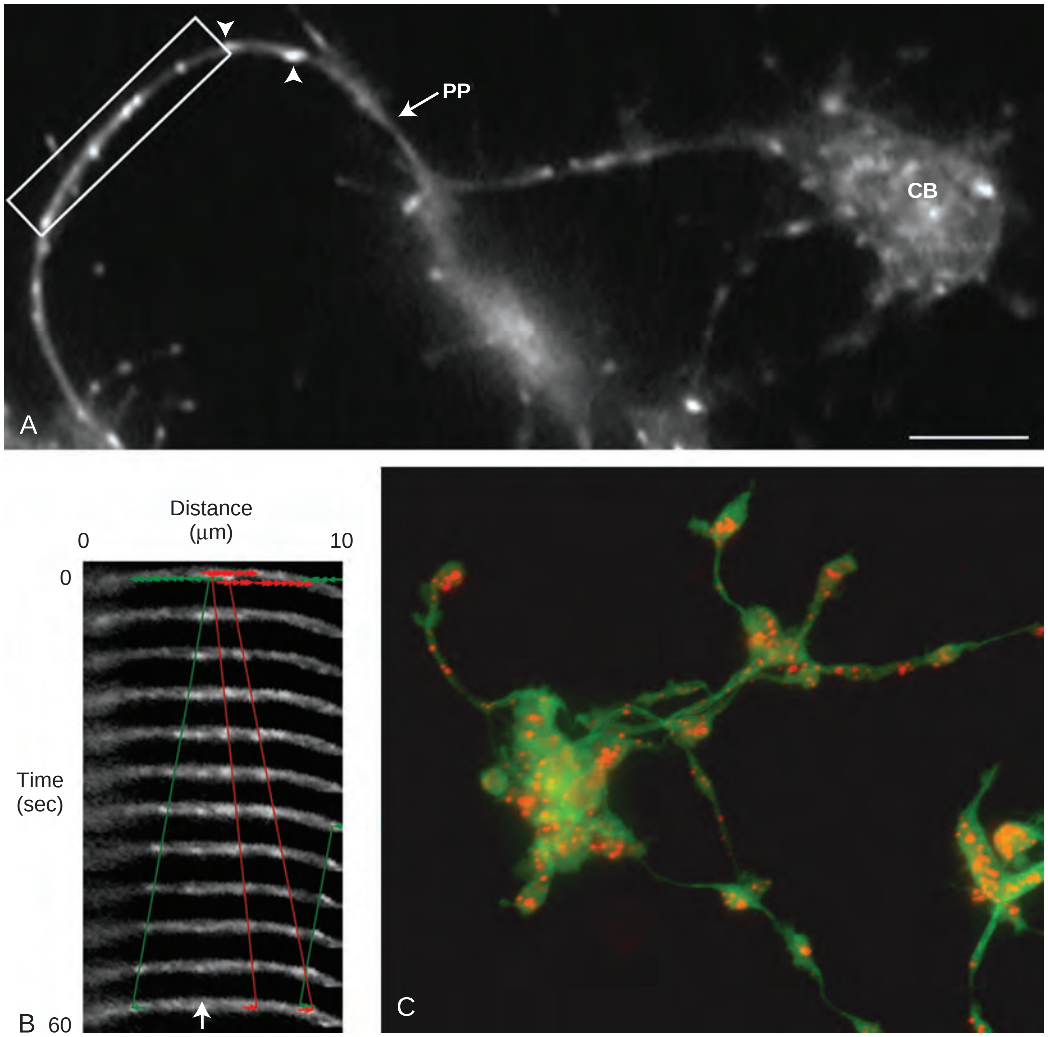

Figure 123.4 MICROTUBULE DYNAMICS DURING PROPLATELET FORMATION. (A) Visualization of plus-end microtubule assembly in living megakaryocytes expressing end-binding protein 3 (EB3)-green fluorescent protein (GFP). First frame from the time-lapse sequence (B) of a living megakaryocyte that was retrovirally directed to express EB3-GFP. The cell body (CB) is at the right of the micrograph, and proplatelets (PP) extend to the left. EB3-GFP labels growing microtubule plus ends in a characteristic "comet" staining pattern that has a bright front and a dim tail. (B) The kymograph shows movement over time. Images are every 5 seconds. EB3-GFP comets undergo bidirectional movements in PP, demonstrating that microtubules are organized as bipolar arrays. Some EB3-GFP comets move toward the tip and are highlighted in green; others that move toward the cell body are highlighted in red. (C) Distribution of α-granules in megakaryocytes and PP projections visualized by fluorescence microscopy. α-Granules are stained with Alexa 568 *(red)*–labeled anti–von Willebrand factor antibodies. The proplatelets have been co-stained with Alexa 488 *(green)* antitubulin antibodies to highlight the microtubules.

biogenesis are regulated at multiple levels by several cytokines. TPO, which is synthesized in the bone marrow and liver, is the principal regulator of thrombopoiesis. TPO also plays a central role in hematopoietic stem cell survival and proliferation. Circulating levels of TPO induce proliferation and maturation of megakaryocyte progenitors by binding to the c-Mpl (myeloproliferative leukemia protein) receptor and signaling induction. TPO regulates all stages of megakaryocyte development, from the hematopoietic stem cell stage through cytoplasmic maturation. TPO increases platelet production by increasing both the number and size of individual megakaryocytes. However, it is important to note that TPO plays no role in triggering megakaryocytes to make proplatelets or to release platelets. c-Mpl activation is regulated by a complex array of signaling molecules that turn on specific transcription factors (see Transcriptional Regulation of Platelet Formation later in this chapter) to drive megakaryocyte proliferation and maturation. Although TPO appears to function as the main regulator of megakaryocyte development, it is not exclusive in this action. The cytokine stem cell factor, granulocyte-macrophage colony-stimulating factor, FLT (fms related receptor tyrosine kinase 1) ligand, interleukin (IL)-1, IL-3, IL-6, IL-11, CCL5, and erythropoietin also can regulate megakaryocyte development but appear to function mainly in concert with TPO. Mice that lack TPO or its receptor c-Mpl have approximately 15% of the normal platelet count. The discovery of TPO in 1994 and the development of primary megakaryocyte or mouse embryonic stem cell cultures that can be induced to faithfully reconstitute platelet formation has provided systems for studying megakaryocytes in the act of making platelets in vitro. Megakaryocytes isolated from mouse fetal liver and incubated with TPO for 4 to 5 days mature into large polyploid cells that are capable of generating and releasing large numbers of platelets. In a similar fashion, mouse embryonic stem cells can be induced to mature into polyploid megakaryocytes in the presence of stromal cells and TPO, IL-6, and IL-11. This process requires 10 to 12 days, during which the conversion of embryonic stem cells into hematopoietic stem cells very likely occurs in the first half of the time and the maturation of hematopoietic stem cells into proplatelet-producing megakaryocytes in the second half. Human embryonic stem cells can be coaxed to differentiate into mature megakaryocytes,[3] although the process takes several more days in culture. Recently, platelets have been generated from induced human pluripotent stem cells in culture using a doxycycline-controlled c-MYC expression vector.[4]

PLATELET FORMATION

Proplatelets and the Cytoskeletal Mechanics of Platelet Formation

The discovery of TPO and the development of megakaryocyte cultures that reconstitute platelet formation in vitro have allowed visualization of megakaryocytes in the act of forming platelets.[5] The actual mechanical process of platelet production begins when mature megakaryocytes start to elaborate proplatelets (see Fig. 123.2 and Fig. 123.5). This process is distinguished by the erosion of one pole of the megakaryocyte cytoplasm (see Fig. 123.5). Multiple thick pseudopodia are extended and subsequently elongate to yield thin tubules. As these slender tubules grow, they branch repeatedly and develop periodic densities along their length that impart a beaded appearance.[5,6] One of the first insights into the cytoskeletal mechanics of platelet formation comes from the work of Tablin and colleagues, who showed that proplatelet formation is dependent on microtubules; that is, proplatelet elaboration is inhibited by microtubule poisons. Microtubule poisons are effective because the extension of proplatelets from the megakaryocyte is mediated by the assembly of microtubules and their reorganization into cortical bundles. Cortical bundles align in the shafts of proplatelets, and proplatelet elongation is driven by sliding movements between overlapping microtubules composed of these bundles.[7] The microtubule bundles form loops at the end of each proplatelet, and ultimately a single microtubule is rolled into a coil at the proplatelet end to define the platelet territory. Cytoplasmic tubulin in solution is an αβ dimer that reversibly polymerizes into microtubules, which are long, hollow cylinders with an outer diameter of 25 nm. Many studies have confirmed an essential role in platelet biogenesis for β_1 tubulin, a divergent and lineage-specific β tubulin that is a major component of the megakaryocyte proplatelet cytoskeleton and marginal microtubule coil of the platelet. β_1 Tubulin, which is expressed exclusively in platelets and megakaryocytes during the late stages of megakaryocyte development, is essential for production of normal numbers of platelets, as well as for the discoid shape of platelets. The evidence supporting the role of β_1 tubulin in these processes comes from several sources. First, messenger RNA (mRNA) subtraction between wild-type and nuclear factor, erythroid 2 (NF-E2)–deficient megakaryocytes identifies β_1 tubulin as a downstream effector of the megakaryocyte transcription factor NF-E2 that is absent in NF-E2–deficient megakaryocytes. Second, genetic elimination of the β_1-tubulin gene in mice results in thrombocytopenia.[6] Third, megakaryocytes isolated from β_1-tubulin knockout mice fail to form proplatelets in vitro and instead extend only a small number of blunt protrusions.

The first event that signals proplatelet production is the consolidation of microtubules into large bundles at the megakaryocyte cortex that subsequently are reorganized into parallel bundles in the shafts of the proplatelets (Fig. 123.6).[8] Microtubule bundles are thick near the body of the megakaryocyte as they enter the proplatelet shaft but become progressively thinner along the shaft, such that only 5 to 10 microtubules remain at the end of the proplatelet. Of note, the microtubule bundles that run down the proplatelet shaft make characteristic U turns in the tips and reenter the shaft, forming teardrop-shaped structures (Fig. 123.7). This creates a bipolar orientation of bundles near the proplatelet tip, a geometry required to explain the bidirectional granule and organelle traffic observed in proplatelets. The looped arrangement of microtubules in proplatelet tips also constrains the elongation mechanism used to grow proplatelets because of an insufficient number of free microtubule ends to nucleate this reaction.

Direct visualization of microtubule dynamics in living megakaryocytes using green fluorescent protein (GFP) technology has provided insights into how microtubules orient to power proplatelet elongation (see Fig. 123.4A and B). End-binding protein 3 (EB3), a microtubule plus end–binding protein associated only with growing microtubules, fused to GFP, was retrovirally expressed in murine megakaryocytes and used as a marker to localize microtubule plus ends and to follow plus end dynamics.[7] Immature megakaryocytes without proplatelets use a centrosomal-coupled microtubule nucleation/assembly reaction, which appears as a prominent starburst pattern when visualized with EB3-GFP. Microtubules assemble only from the centrosome and grow outward into the cell cortex, where they turn and run parallel to the cell edges. However, just before proplatelet production begins, centrosomal assembly ends and microtubules release and consolidate into the cortex as bundles. Fluorescence time-lapse microscopy of living, proplatelet-producing megakaryocytes expressing EB3-GFP reveals that as proplatelets elongate, microtubules assemble continuously throughout the entire proplatelet. EB3-GFP studies also reveal that microtubules polymerize in both directions in proplatelets (i.e., toward both the tips and cell body), demonstrating that microtubules composing the bundles have a mixed polarity. The cytoplasmic Ran-binding protein, RanBP10, is a β_1-tubulin–binding protein that appears to regulate the assembly of proplatelet microtubules.[9] Even though microtubules are continuously assembling at their plus ends in proplatelets, polymerization per se does not provide the force for proplatelet elongation. First, the rates of microtubule polymerization (average 10.2 μm/min) are approximately 10-fold faster than the proplatelet elongation rate. Second, proplatelet elongation continues when microtubule polymerization is blocked with drugs that inhibit net assembly, suggesting an alternative mechanism for proplatelet elongation. Third, proplatelets possess an inherent microtubule sliding mechanism. Cytoplasmic dynein, a minus-end microtubule molecular motor protein, localizes along the microtubules of the proplatelet and appears to directly contribute to microtubule sliding; inhibition of dynein through disassembly of the dynactin complex prevents proplatelet formation. Microtubule sliding can be reactivated in detergent-permeabilized proplatelets with adenosine triphosphate, which is known to support the enzymatic

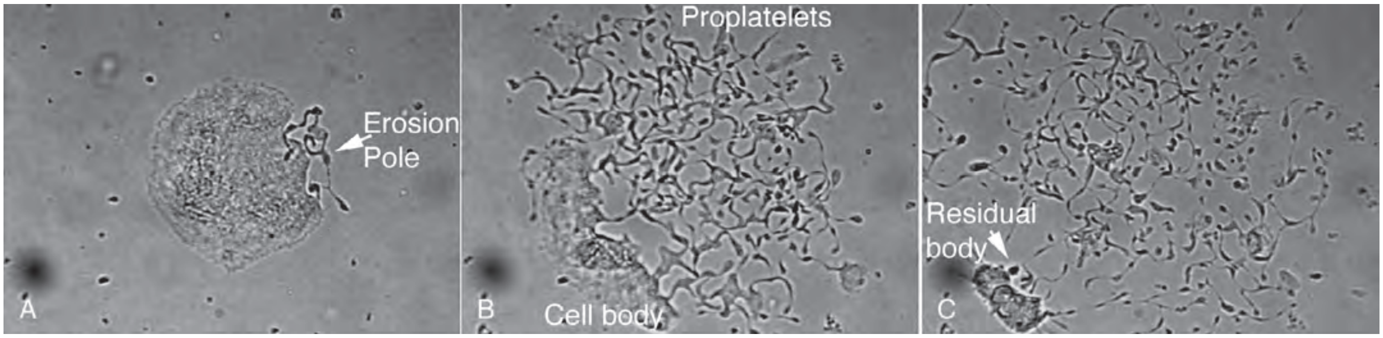

Figure 123.5 FORMATION OF PROPLATELETS BY A MOUSE MEGAKARYOCYTE. Time-lapse sequence of a maturing megakaryocyte showing the events that lead to elaboration of proplatelets in vitro. (A) Platelet production begins when the megakaryocyte cytoplasm starts to erode at one pole *(arrow)*. (B) The bulk of the megakaryocyte cytoplasm has been converted into multiple proplatelet processes that continue to lengthen and form swellings along their length. These processes are highly dynamic and undergo bending and branching. (C) Once the bulk of the megakaryocyte cytoplasm has been converted into proplatelets, the entire process ends in a rapid retraction that separates the released proplatelets from the residual cell body.

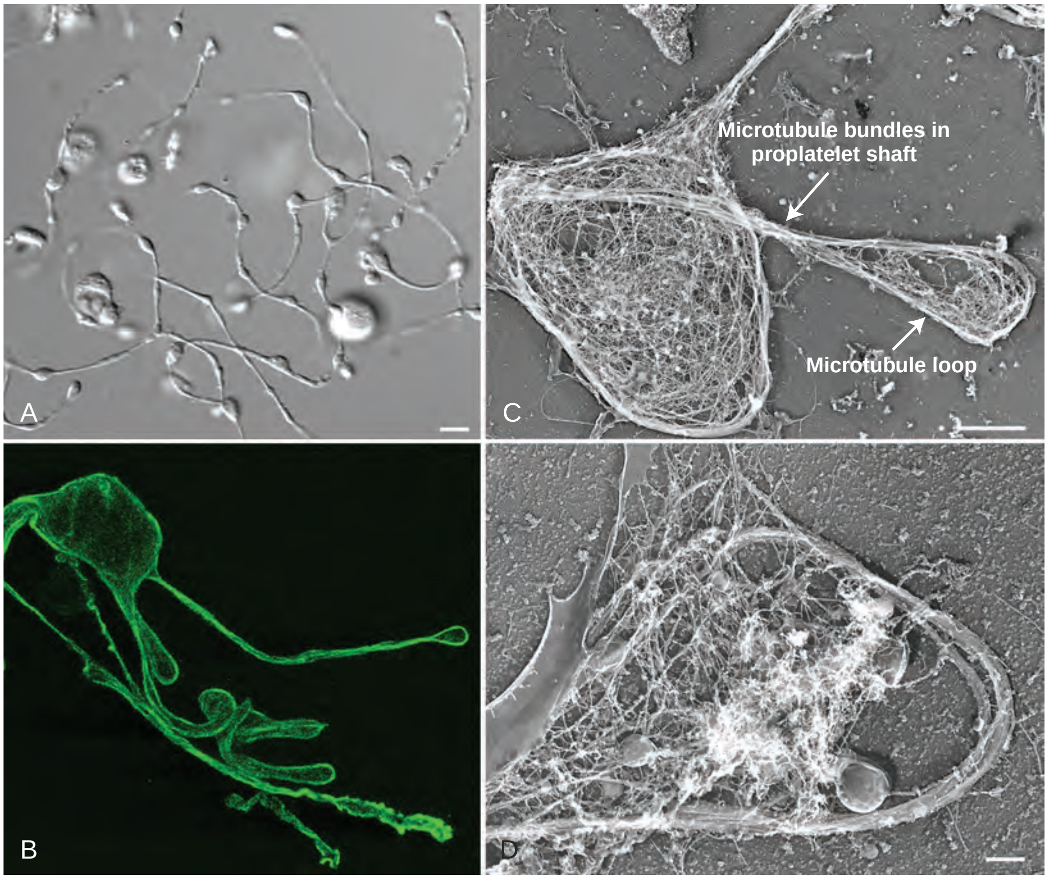

Figure 123.6 STRUCTURE OF PROPLATELETS. (A) Differential interference contrast image of proplatelets elaborated by mouse megakaryocytes in culture (bar = 5 μm). (B) Staining of proplatelets with Alexa 488 antitubulin immunoglobulin G reveals that the microtubules line the shaft of the proplatelet and form loops at the proplatelet tips (bar = 5 μm). (C, D) Organization of microtubules in the tips of proplatelets. (C) Microtubules form bundles in the proplatelet shafts (bar = 2 μm). (D) Microtubules loop in the proplatelet ends and reenter the proplatelet shafts (bar = 0.2 μm).

activity of microtubule-based molecular motors and activates elongation in permeabilized proplatelets that contain dynein and its regulatory complex dynactin. More recent analysis has indicated six types of behaviors that characterize the elaboration of proplatelets: elongation, branching, pausing, fusions, fragmentations, and retractions. While the average elongation rate for proplatelets over time is 1 μm/min, extension normally occurs in bursts and pauses. Burst rates greatly exceed the average rates, and under flow rates of less than 30 μm/min have been observed. These rates correlate well with the sliding rates of microtubules within the bundles. Fluorescence recovery after photobleaching studies have demonstrated that microtubule sliding drives proplatelet elongation and is dependent on cytoplasmic dynein.[32] Thus dynein-facilitated microtubule sliding appears to be the key event driving proplatelet elongation.

Nascent platelets assemble at the bulbous ends of proplatelets, as defined by the rolling of a single microtubule into a coil having the same diameter as the coil found in the mature platelet. Given that maturation of the platelet is limited to these sites; efficient platelet production requires a large number of proplatelet ends. In vitro, megakaryocytes use a unique mechanical process to repeatedly bifurcate the shafts of the proplatelet, thereby amplifying the number of ends. To accomplish this task, the shaft of elongating proplatelets is bent on itself and a new proplatelet grows out of the bend—a process that results in bifurcation of the shaft. Proplatelet elongation is mediated by microtubules, whereas actin mediates the bending and branching of proplatelet shafts. Actin filament assemblies decorate branch points, and agents that disrupt actin assembly, such as the cytochalasins, reduce proplatelet branching. One possibility is that in vitro proplatelet bending and branching are regulated by the actin-based molecular motor myosin. Myosin II is an adenosine triphosphatase (ATPase) motor that makes up 2% to 5% of the total platelet protein. Myosin II binds to actin filaments and generates force for contraction. Each myosin has two heads and a long, rod-like tail whose function is to permit the molecules to assemble into bipolar filaments. Of interest, a mutation in the tail domain of the nonmuscle myosin heavy chain A gene in humans results in several disorders, including May-Hegglin anomaly, Sebastian syndrome, and Fechtner syndrome. These rare autosomal platelet disorders are characterized by thrombocytopenia with giant platelets. Recent findings have implicated myosin IIA in restricting proplatelet production until megakaryocytes attain full maturity. The loss of myosin IIA function through targeted gene disruption in mice, through dominant inhibitory mutations in humans, or by manipulation of cultured megakaryocytes, appears to accelerate proplatelet production. Consequently, platelet production is inefficient and produces platelets that vary extensively in shape, content, and diameter. These findings also suggest that the Rho-ROCK-myosin light chain pathway regulates myosin IIA.

Experiments also indicate that protein kinase Cα associates with aggregated actin filaments in megakaryocytes and negatively regulates proplatelet formation.[33] Recently, we identified a novel protein, MARCKS (myristoylated alanine-rich C-kinase substrate), that is a downstream target of protein kinase Cα and regulates the process of actin polymerization in megakaryocytes.[34] MARCKS attaches to phosphatidylinositol 4,5-bisphosphate $(PIP)_2$ rafts, limiting their availability to bind WASp and blocking activation of the actin-related protein 2/3 complex (Arp2/3) actin nucleating complex. Upon phosphorylation, MARCKS is internalized and PIP_2 is free to bind WASp, thus activating the Arp2/3 complex and initiating actin polymerization. In this way, MARCKS phosphorylation may provide a fast way to activate or inhibit actin polymerization, when necessary, over the course of proplatelet production. However, the role of actin filament dynamics in platelet biogenesis remains unclear.

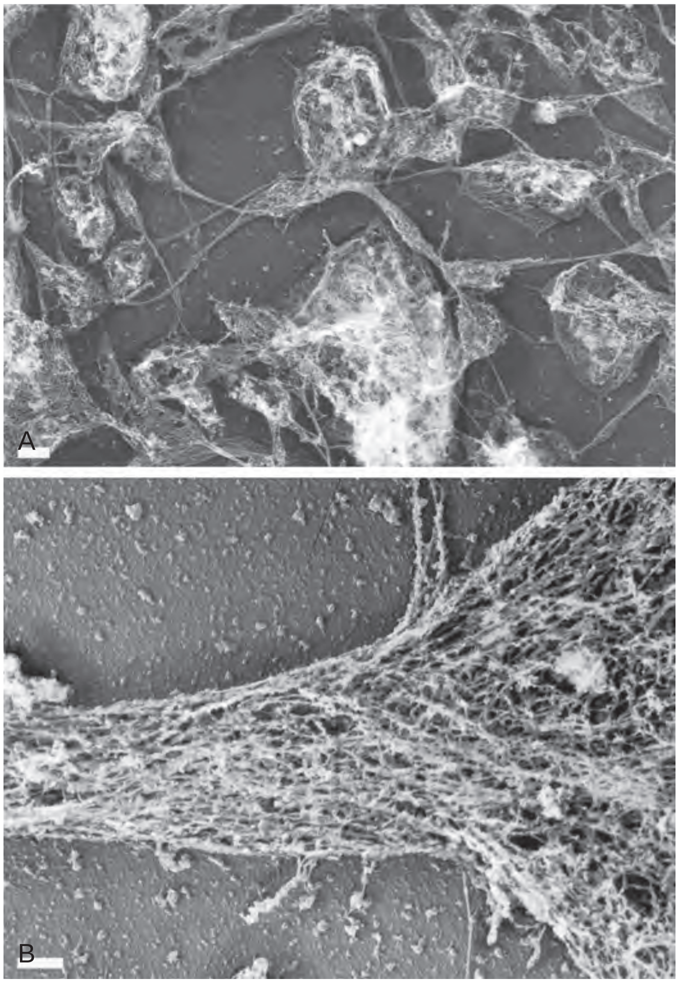

Figure 123.7 MEMBRANE SKELETON OF THE PROPLATELET. Representative electron micrographs of the detergent-insoluble proplatelet cytoskeleton. Proplatelets were permeabilized with 0.75% Triton X-100, 5 μM phallacidin, and 0.1% glutaraldehyde. Examination through electron microscopy reveals that the plasma membrane of the proplatelet tube is supported by a fibrous membrane skeleton that is similar in structure to the membrane skeleton of mature platelets. (A) This low-magnification field shows that an intact membrane skeleton laminates the underside and extends along the entire length of proplatelets (bar = 1 μm). (B) High-magnification, three-dimensional electron micrograph of the proplatelet membrane skeleton reveals a lattice-like network of elongated filamentous strands, similar in nature to the spectrin-based network in red blood cells and platelets. The membrane skeleton continuously laminates the underside of the proplatelet. A cytoplasmic bridge is shown *(left)* linking to a swelling *(right)* (bar = 200 nm).

Profilin is a small actin-binding protein that stimulates filament polymerization. It binds ADP, converting them to adenosine triphosphate (ATP) monomers, which interact only with the high-affinity end of actin filaments. Mice whose megakaryocytes/platelets specifically lack profilin 1 have macrothrombocytopenia, with counts reduced by 40% to 50%. Platelet turnover is accelerated, and the mature platelets have only a sparse internal actin cytoskeleton. Although their actin cytoskeleton is disrupted, platelets missing profilin have a hardy microtubule cytoskeleton with a thickened microtubule coil and more stable hyperacetylated microtubules.[35] In some ways, platelets from profilin 1–deficient mice are similar in behavior to platelets from patients with Wiskott-Aldrich syndrome or those from WASp- or WIP (WASp-interacting protein)-deficient mice. WASp is a signaling protein that promotes actin assembly, binding to Arp2/3 when activated by binding of GTP-Cdc42. However, most studies performed on human Wiskott-Aldrich syndrome platelets or platelets derived from WASp-deficient mice revealed normal and even hyperfunctionality for the WASp-null platelets.[36,37] Humans with Wiskott-Aldrich syndrome have low platelet counts as a consequence of accelerated platelet clearance, a process that also lowers the platelet count in WASp/WIP-deficient mice. Studies have shown that the microtubule coils in platelets from Wiskott-Aldrich syndrome patients are hyperacetylated, like those in platelets from profilin 1 deficient mice. However, in Wiskott-Aldrich syndrome, circulating platelets are small, and not large as observed in profilin 1–deficient mice.

Human Arp2/3 attaches to and is activated by WASp family proteins, where it acts as an initiation site for new actin filaments and is required for actin filament branching. Arp2/3 has two ARPC1 (actin-related protein C1) component isoforms, with ARPC1B prominently expressed in blood cells. Recently, a report was published on three individuals from two families with homozygous mutations in ARPC1B.[38] Patients present with defective Arp2/3 actin filament branching that is associated with multisystem disease including platelet abnormalities, cutaneous vasculitis, eosinophilia, and a predisposition to inflammatory diseases. The Arpc2 gene was knocked out in murine platelets, and as observed in the patients, this was associated with significant microthrombocytopenia as a result of premature release of platelets into the bone marrow and reduced platelet survival.[39] Not surprisingly, because WASp and Arp2/3 are binding partners, this phenotype largely phenocopies that of WASp/WIP-deficient mice.

Another actin-binding protein that plays a significant role in platelet generation and structure is filamin A. Filamin A is a large cytoplasmic protein that crosslinks actin filaments into arrays and attaches the vWF receptor (GPIb-IX-V) to the underlying actin cytoskeleton. Filamin subunits are elongated strands made up of 24 repeats, each approximately 100 amino acids in length that are folded into immunoglobulin G (IgG)-like beta barrels. There are three filamin genes on chromosomes 3, 7, and X. Filamin A (X) and filamin B (3) are expressed in platelets, with filamin A being present in a greater than 10-fold excess over filamin B. The second rod domain of filamin has a binding site for the cytoplasmic tail of GPIbα, and biochemical experiments have shown that the majority of platelet filamin (≧90%) is in complex with GPIbα. Knockout of the filamin A gene in the megakaryocyte lineage of mice leads to low platelet count with giant platelets.[40] Filamin A–null megakaryocytes release platelets more rapidly than wild-type megakaryocytes, and the severe macrothrombocytopenia appears to be caused by the rapid clearance of platelets and by the spontaneous formation of platelet microvesicles. These observations suggest that filamin A–null megakaryocytes prematurely produce large and fragile platelets that are rapidly removed from the bloodstream.

In addition to proteins that promote actin assembly and structural organization, there is also strong evidence that proteins that stimulate actin filament assembly play a major role in platelet production. Members of the actin-depolymerizing factor (ADF) cofilin family are known to play an essential role in temporally and spatially regulating the turnover of actin filaments in all species. The importance of filamentous actin severing proteins in platelet production has been established. Deletion of all ADF/n-cofilin dynamics in megakaryocytes virtually abolishes platelet formation and results in the formation of both giant and microparticle-like platelets with aberrant ultrastructure.

In addition to proteins that promote actin assembly and structural organization, there is also strong evidence that proteins that stimulate actin filament assembly play a major role in platelet production. Members of the ADF cofilin family play an essential role in temporally and spatially regulating the turnover of actin filaments in all mammals. Deletion of all ADF/n-cofilin dynamics in megakaryocytes virtually abolishes platelet formation and results in the formation of both giant and microparticle-like platelets that are characterized by aberrant ultrastructure.[41] Proplatelet production is highly reduced in ADF/n-cofilin–null megakaryocytes. Defective proplatelet production has also been observed in mice in which the small regulatory GTPases Rho, Cdc42, and Rac have been deleted in the megakaryocyte lineage.[42,43] All told, these observations suggest that in vivo actin filament turnover is an essential step in the end stages of platelet generation.

In addition to playing an essential role in proplatelet elongation, the microtubules lining the shafts of proplatelets serve a secondary function: transport of membrane, organelles, and granules into proplatelets and assembling platelets at proplatelet ends (see Fig. 123.4C). Organelles are sent individually from the cell body into the proplatelets, where they move bidirectionally until they are captured at proplatelet tips.[14] Immunofluorescence and electron microscopic studies indicate that organelles are intimately associated with microtubules, and actin poisons do not diminish organelle motion. Thus movement appears to involve microtubule-based forces. Bidirectional organelle movement is conveyed in part by the bipolar arrangement of microtubules within the proplatelet because kinesin-coated latex beads move in both directions over the microtubule arrays of permeabilized proplatelets. Of the two major microtubule motors, kinesin and cytoplasmic dynein, only the plus end–directed kinesin is localized in a pattern similar to organelles and granules and is therefore likely responsible for transporting these elements along microtubules. It appears that two mechanisms of organelle and granule movement are involved in platelet assembly: first, organelles and granules travel along microtubules and, second, the microtubules themselves slide bidirectionally in relation to other motile filaments, indirectly moving organelles along proplatelets in a piggyback manner.

Although the roles of microtubules and actin filaments in proplatelet development have been extensively studied, our understanding of the function of the membrane skeleton has only recently been established. High-resolution electron microscopy reveals that proplatelets have a dense spectrin-based membrane skeleton similar in structure to that of mature blood platelets. Nonerythroid spectrin subunits, alpha-II and beta-II spectrin, are predominately expressed in mouse megakaryocytes, proplatelets, and platelets, but erythroid alpha-I and beta-I spectrin isoforms are also expressed (see Fig. 123.6).[15] Assembly of spectrin tetramers is required for development of the DMS and proplatelet elaboration because expression of a spectrin tetramer–disrupting construct in megakaryocytes inhibits both processes. Furthermore, integration of this spectrin-disrupting construct into a permeabilized proplatelet system quickly destabilizes proplatelets, resulting in massive blebbing and swelling. Spectrin tetramers also stabilize the barbell-like shapes found in the penultimate stage in platelet production. Taken together, these studies suggest a role for spectrin in different steps of megakaryocyte development through its participation in the formation of demarcation membranes and in the maintenance of proplatelet structure.

Platelet Maturation at the Proplatelet Tip

Platelet maturation at proplatelet tips ends when a single microtubule detaches from the microtubule bundle and is rolled into a coil. To complete construction of mature platelets, once the fundamental cytoskeletal components have been delivered to and assembled in the platelet buds, the buds must fill with their organelle and granule content.

Granules are sent to nascent platelets on the microtubule tracks of the proplatelets. The concentration of this cargo in the platelet occurs by an end-trapping mechanism as granules and organelles, which enter the nascent platelet, continue to move in the tip but do not return to the proplatelet shaft.

Release of Mature Platelets

Details of how mature platelets release from the proplatelet tips are beginning to come into focus. In vitro, maturation of proplatelets ends in a rapid retraction that separates a variable portion of the proplatelets from the residual cell body, leaving behind a naked, denuded nucleus (see Fig. 123.5C). Activation of apoptotic pathways in the cell body has been shown to be coincident with this event. Junt and colleagues have used intravital fluorescence microscopy to visualize proplatelet production in the opened cranial marrow cavity of living mice.[16] Yellow fluorescent protein (YFP)-labeled megakaryocytes were seen to protrude proplatelets and release megakaryocyte fragments into the marrow sinusoids of living mice. Notably, these anucleate fragments typically exceed platelet dimensions, suggesting that platelet morphogenesis continues in the circulation. In line with these observations, we identified a previously unrecognized intermediate stage in platelet formation and release, which we termed the *preplatelet*.[17] Preplatelets are defined as discoid cells (3 to 10 μm) that retain the capacity to convert into barbell-shaped proplatelets and undergo fission into platelets. The conversion of preplatelets to barbell proplatelets is powered by microtubule-based forces. It is likely that the microtubule motors that drive proplatelet extension are involved in aspects of platelet release, as well as in the process of microtubule coiling. Sliding of an uncoiled portion of the microtubule relative to the rigid microtubule bundle in the proplatelet tip would provide a simple mechanism to effect platelet release and would explain the variable morphology of the small but reproducible percentage (<5%) of dumbbell-shaped platelets that are present in blood. The morphologic similarities between platelets that form new cell bodies and preplatelets are striking. Whether or not newly released platelets exhibit a preplatelet phenotype, which allows them to form barbell shapes and divide again, is not clear.

Location of Platelet Release

Megakaryocytes cultured in vitro outside the confines of the bone marrow can form developed proplatelets in solution, suggesting that direct interaction with the marrow environment is not essential for platelet production. However, the efficiency of platelet production in culture appears to be diminished relative to that observed in vivo, and the bone marrow environment, which contains a complex cell population, could influence platelet formation by direct cell contact or secretion of cytokines. It has been suggested that, by extending into the bone marrow sinusoids, proplatelets provide a mechanism for extension into the bone, allowing release of platelets directly into the circulation.[19,20] Scanning electron micrographs have revealed bone marrow megakaryocytes extending proplatelets through junctions in the endothelium into the sinusoidal lumen, supporting the concept that platelet production occurs in the bone marrow. Megakaryocytes have been observed in the lung, prompting the notion that platelets can be formed from their parent cells in the pulmonary circulation. Aschoff initially described pulmonary megakaryocytes in 1893 and suggested that they originated in the marrow, migrated into the bloodstream, and, because of their massive size, became lodged in the pulmonary capillaries, where they released platelets. This mechanism requires the migration of megakaryocytes from the bone marrow into the circulation, which had not been observed by intravital microscopy. Lefrancais[44] and colleagues used two-photon intravital microscopy to visualize the lung in mice in which platelet factor 4-Cre recombinase (PF4-Cre) drives membrane GFP expression in megakaryocytes and platelets. They observe large circulating GFP^+ cells passing through the lung microcirculation, where they produce GFP^+ proplatelet extensions in a flow-dependent manner. To investigate the derivation of these pulmonary megakaryocytes, they used an orthotopic single lung transplant model and found that the megakaryocytes producing platelets in the lung circulation are of extrapulmonary origin, the majority of which originated from the bone marrow. However, studies using accelerated models of thrombopoiesis in mice suggest that only a small fraction of platelet production occurs in the lung.[45] In addition, removal of a lung in mice or humans does not alter the platelet count. It is also worth noting that patients with pathologic conditions of the lung such as chronic obstructive pulmonary disease, pulmonary tuberculosis, and cystic fibrosis do not have decreased platelet counts; in fact, these patients often present with elevated platelet counts (thrombocytosis).[46–48] Together, these murine and human data suggest that the lung is not the primary site of platelet production.

Transcriptional Regulation of Platelet Formation

Megakaryocyte development and platelet formation are controlled by the coordinated action of transcription factors that specifically turn on the genes of megakaryocyte precursors or suppress the expression of genes that support other cell types.[22] Gene-targeting studies in mice have identified several genes that are crucial for megakaryocyte development and platelet formation. Leading the list of transcription factors that play an essential role in megakaryocyte maturation and platelet biogenesis is the basic leucine zipper heterodimer NF-E2. NF-E2 is a protein composed of a ubiquitously expressed 18- to 20-kDa small-Maf subunit and a p45 subunit that is restricted to erythroid and megakaryocytic lineages. Although NF-E2 was postulated to be a transcription factor that specifically drove the expression of genes essential for erythropoiesis, mice lacking p45 NF-E2 do not exhibit defects in erythropoiesis. Instead, mice deficient in the p45 subunit or two of the small-Maf subunits die of hemorrhage shortly after birth because of a complete lack of circulating platelets. Although megakaryocytes undergo normal endomitosis and proliferate in response to TPO, mice deficient in p45 NF-E2 produce increased numbers of megakaryocytes that are larger than normal, contain fewer granules, exhibit a highly disorganized DMS, and fail to generate proplatelets in vitro, a phenotype indicative of a late block in megakaryocyte maturation. Therefore NF-E2 appears to control the transcription of a limited number of genes involved in cytoplasmic maturation and platelet formation. Shivdasani and colleagues generated a subtracted complementary DNA (cDNA) library enriched in transcripts downregulated in NF-E2–knockout megakaryocytes. Using this approach, these investigators have started to identify the downstream targets of NF-E2 and to analyze their role in the terminal stages of megakaryocyte differentiation. Putative transcriptional targets of NF-E2 include β_1-tubulin, thromboxane synthase, and proteins that regulate inside-out signaling via $\alpha_{IIb}\beta_3$ integrin. The zinc finger protein GATA1 is also a transcription factor that plays a critical role in driving the expression of genes essential for megakaryocyte maturation. However, unlike NF-E2, which appears to drive the later stage of megakaryocyte development, *GATA1* functions at multiple stages of development. Initially, GATA proteins were thought to regulate red blood cell maturation because genetic disruption of the *GATA1* gene in mice results in embryonic lethality secondary to a block in erythropoiesis. However, several more recent observations also implicate *GATA1* as a regulator of megakaryocyte differentiation. First, forced expression of *GATA1* in the early myeloid cell line 416b induces megakaryocyte differentiation. Second, Shivdasani and colleagues used targeted mutagenesis of regulatory elements within the *GATA1* locus to generate mice with a selective loss of *GATA1* in the megakaryocyte lineage. These knockdown mice expressed sufficient amounts of *GATA1* in erythroid cells to circumvent the embryonic lethality caused by anemia. *GATA1* deficiency in megakaryocytes leads to severe thrombocytopenia. Platelet counts are reduced to approximately 15% of normal, and the small numbers of circulating platelets are round and larger than normal. These mice have increased numbers of small megakaryocytes that exhibit an accelerated rate of proliferation. The small cytoplasmic volume of *GATA1*-deficient megakaryocytes typically contains an excess of rough endoplasmic reticulum, very few platelet-specific granules, and an underdeveloped or disorganized DMS, suggesting that maturation of megakaryocytes is arrested in GATA1-deficient megakaryocytes.

A family with X-linked dyserythropoietic anemia and thrombocytopenia due to a mutation in *GATA1* has been described. A single-nucleotide substitution in the N-terminal zinc finger of *GATA1* inhibits the interaction of *GATA1* with its essential cofactor, friend of *GATA1* (FOG). Although megakaryocytes in affected family members are abundant, they are unusually small and exhibit several abnormal features, including an abundance of smooth endoplasmic reticulum, an underdeveloped DMS, and a lack of granules. These observations suggest an essential role for the *FOG1-GATA1* interaction in thrombopoiesis. Genetic elimination of FOG in mice unexpectedly results in specific ablation of the megakaryocyte lineage, suggesting a *GATA1*-independent role for FOG in the early stages of megakaryocyte development; therefore *GATA1* and FOG are required for megakaryocyte generation from a common bipotential progenitor.

The results from several knockout mice models also indicate a role for additional transcription factors in megakaryocyte development. Mice carrying a null mutation in *Fli-1*, a member of the ETS family of winged helix-turn-helix transcription factors that bind purine-rich sequences in gene promoters, exhibit defects in megakaryocyte development. Megakaryocytes cultured from mice lacking *Fli-1* contain reduced numbers of α-granules, disorganization of the demarcation membranes, and a reduction in size. Mice lacking the hematopoietic zinc finger (Hzf) protein, a transcription factor that is predominantly expressed in megakaryocytes, have reduced numbers of α-granules in megakaryocytes and platelets. Therefore Hzf may regulate the transcription of genes involved in the synthesis of α-granule components and/or their packaging into α-granules. SCL (stem-cell leukemia), a basic helix-loop-helix transcription factor initially identified in a subset of human T-cell leukemia with multilineage characteristics, also appears to be critical for megakaryopoiesis. Results of deletion of SCL in mice indicate that this transcription factor is required for proper erythroid and megakaryocyte development.

PLATELETS

Structure of the Resting Platelet

Megakaryocyte development culminates in the release of proplatelets that are remodeled into mature discoid platelets having dimensions of approximately 3.0 × 0.5 μm and a cytoplasmic volume of 7 fL.[23] The evolutionary explanation for the discoid shape of the platelet is unknown. Discoid shape may permit more efficient flow or dispersion of clot-promoting elements or may simply reflect the microtubule-based mechanism by which platelets are produced. In humans, platelets normally circulate for 7 to 10 days. Given that nearly 1 trillion platelets circulate in an adult human, an adult produces approximately 100 billion platelets each day.

The precise morphology of newly released platelets is unknown. However, when released into the circulation or maintained in culture, platelets have a reproducible structure. Although they are heterogeneous in size, platelets have discoid shapes with flat, featureless surfaces (Figs. 123.8A and 123.9A) that are interrupted only by pit-like openings into the open canalicular system (OCS). The OCS is an extensive system of internal membrane conduits that serves as a passageway to the outside world into which granular contents are released. It also is a reservoir of plasma membrane, membrane receptors, and proteins. For example, approximately 30% of the thrombin receptors are localized in the OCS of the resting platelet, awaiting movement to the surface when the cells are activated. Although continuous with the plasma membrane, not all proteins on the cell surface can enter the OCS. Factors controlling movement into the OCS remain to be defined but likely depend on the actin cytoskeleton. However, entry restriction occurs at the necks of OCS infoldings. The third function of the OCS is to serve as a source of redundant plasma membrane for cell spreading. OCS membrane initially is disgorged to the surface following cell activation. When cells are activated in solution, much of this membrane is subsequently reabsorbed into the remnants of the OCS.

A small thin zone of cytoplasm separates the plasma membrane of the resting platelet from a marginal microtubule coil and the general intracellular space, which contains all inclusion bodies and the internal cytoskeleton of the cell. This zone is filled with the spectrin-based membrane skeleton (see Fig. 123.9A). Beneath this zone sits a microtubule coil. Then follows the cytoplasmic space, which is filled with filaments of actin that embed granules, organelles, the OCS, and other specialized membrane systems such as smooth endoplasmic reticulum.

Platelets actively recruit other blood-borne cells to areas of vascular damage by releasing mediators packaged in intracellular granules (described earlier in Cytoplasmic Maturation) that initiate secondary homeostatic interactions and that express a “sticky” apical surface after the platelets adhere. In the resting platelet, granules are juxtaposed together and are in intimate association with the membranes of the OCS. The release reaction of platelet granules differs from that of other cells. Granules rarely fuse with the plasma membrane; instead, they exocytose into the OCS. Platelets also contain lysosomes and mitochondria, which are easily identified under the electron microscope by their internal system of membrane cristae.

Cytoskeleton of the Resting Platelet

Although both microtubule- and actin-based forces have been considered in the elaboration and branching of proplatelets, respectively, it is the integration of the microtubule and actin cytoskeletal elements that uniquely defines the shape of the mature platelet. One of the most distinguishing features of the resting platelet is its marginal microtubule coil (see Fig. 123.8). αβ-Tubulin dimers assemble into microtubule polymers under physiologic conditions. In resting platelets, tubulin is equally divided between dimer and polymer fractions. In many cell types, αββ-tubulin subunits are in a dynamic equilibrium with microtubules such that reversible cycles of assembly-disassembly of microtubules are observed. Microtubules are long, hollow polymers (24 nm in diameter) that are responsible for many types of cellular movements, such as segregation of chromosomes during mitosis and transport of organelles across the cell. The microtubule ring of the resting platelet, initially characterized in the late 1960s by White and Krivit, was described as a single microtubule approximately 100 µm long and is coiled 8 to 12 times inside the periphery of the platelet. However, recent work suggests that the marginal band is highly dynamic and consists of multiple microtubules with mixed polarity that undergo constant assembly and disassembly.[24] This may accommodate the shrinkage of microtubule coil diameters that occurs with aging of platelets. Antagonistic microtubule motors appear to keep the marginal microtubule coil in its resting state.[49] The primary function of the microtubule coil is to maintain the discoid shape of the resting platelet. Disassembly of platelet microtubules with drugs such as vincristine, colchicine, or nocodazole causes platelets to become round and to lose their discoid shape. Cooling the platelets also causes disassembly of the microtubule coil and loss of the discoid shape. Mice lacking β_1 tubulin, the major hematopoietic β-tubulin isoform, produce platelets that lack their characteristic discoid shapes and have defective marginal bands. Genetic elimination of β_1 tubulin in mice results in thrombocytopenia with circulating platelet counts less than 50% of normal. β_1-Tubulin–deficient platelets are spherical in shape, apparently due to shortened marginal bands with fewer coils. Normal platelets possess a marginal band that consists of 8 to 12 coils, whereas β_1-tubulin knockout platelets contain only two to three coils. A human β_1-tubulin functional substitution (AG→CC) inducing both structural and functional platelet alterations has been described. Of note, the Q43P β_1-tubulin variant was found in 10.6% of the general population and in 24.2% of 33 unrelated patients with undefined congenital macrothrombocytopenia. Electron microscopy revealed enlarged spherocytic platelets with a disrupted marginal band and structural alterations. Platelets with the Q43P β_1-tubulin variant showed mild platelet dysfunction with reduced ATP secretion, attenuated thrombin receptor–activating peptide (TRAP)-induced aggregation, and impaired adhesion to collagen under flow conditions.[50] A

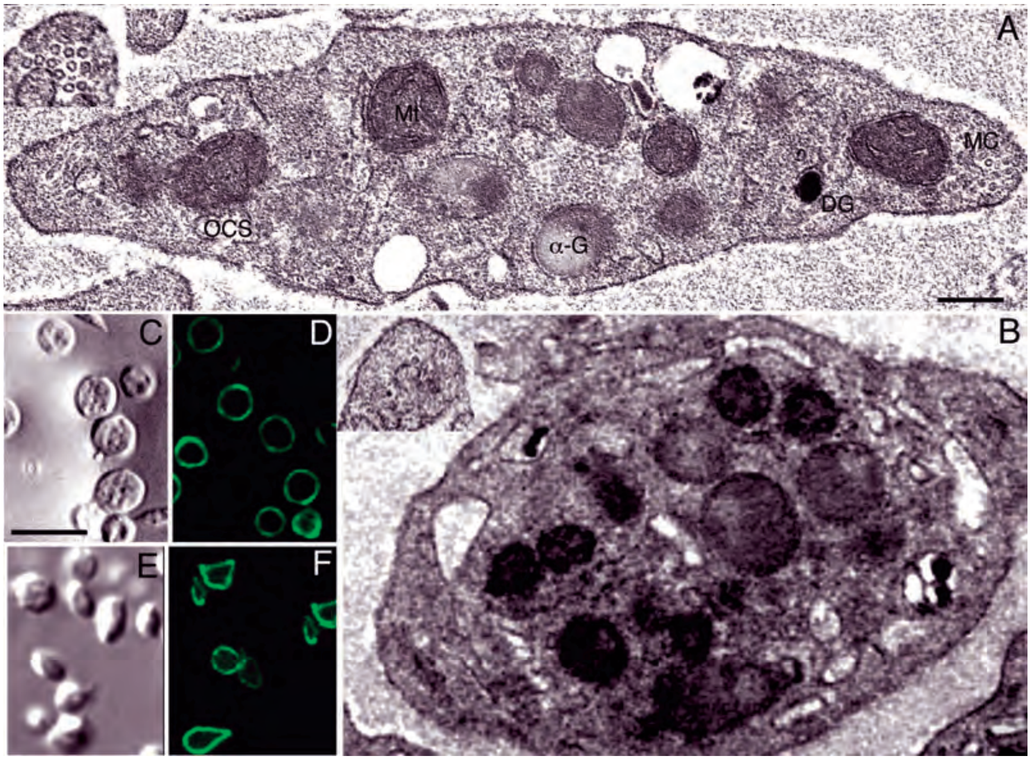

Figure 123.8 COMPARISON OF THE STRUCTURE OF NORMAL MOUSE PLATELETS (A, C, D) WITH THOSE LACKING B_1 TUBULIN (B, E, F). (A) Electron micrograph of a resting mouse platelet sectioned through its thin axis. The cut plane reveals the microtubule coil (MC) at the cell periphery. The *inset* shows a high-magnification cross-section through the MC of the resting platelet. The microtubule is wound 11 times in this platelet, forming the coil. The cytoplasmic space embeds mitochondria *(MT)*, α-granules (α-G), and dense granules *(DG)*. Spaces created by the open canalicular system *(OCS)* are apparent. (B) Electron micrograph of a thin section through a platelet isolated from a mouse lacking β_1 tubulin (bar = 0.2 µm). Platelets from these animals are spherical (E) and have only a rudimentary microtubule coil *(inset)*. In this platelet the microtubule is twisted twice. (C) Differential interference contrast image of resting platelets shows them to be flat discs. (D) MC of the resting mouse platelet. Staining of fixed mouse platelets with Alexa 488 antitubulin immunoglobulin G *(IgG)* reveals the MC. This coil resides at the periphery of the platelet. (E) Differential interference contrast image of platelets lacking β_1 tubulin. (F) Staining of fixed mouse β_1-tubulin–deficient platelets with Alexa 488 antitubulin IgG reveals the coil is defective and bent in a number of places throughout the platelets. (C–F are the same magnification; bar = 5 µm.)

more-than-doubled prevalence of the β_1-tubulin variant was observed in healthy subjects not undergoing ischemic events, raising the possibility that the variant confers an evolutionary advantage and a protective cardiovascular role.

Actin is the most abundant of all the platelet proteins, with 2 million molecules expressed per platelet. Of these molecules, 800,000 assemble to form the 2000 to 5000 linear actin polymers that exist in the resting cell (see Fig. 123.9A). The remainder of the actin is maintained in storage as a 1:1 complex with β_4 thymosin, which can be converted to filaments during platelet activation to drive cell spreading. All evidence indicates that the filaments of the resting platelet are interconnected at various points into a rigid cytoplasmic network because platelets express high concentrations of actin cross-linking proteins, including filamin and α-actinin.[7] Both filamin and α-actinin are homodimers in solution. Three filamin genes are located on chromosomes 3, 7, and X. Filamin A (X) and filamin B (3) are expressed in platelets. Filamin A is expressed at levels more than 10-fold higher than that of filamin B. Filamin subunits are elongated strands composed primarily of 24 repeats, each approximately 100 amino acids in length and folded into IgG-like β-barrels. Each strand has an N-terminus actin-binding site that shares homology with other actin-binding proteins, two rod domains that are end-to-end assemblies of the repeat units, interrupted by two hinge domains between repeats 15 and 16, and 23 and 24, and a C-terminus self-association site (Fig. 123.10B). Subunits assemble to form V-shaped bipolar molecules (i.e., the self-association site is the vertex of the V), and the actin-binding sites are on the free ends. Inclusion of the first hinge in filamin depends on alternative RNA splicing. Filamin now is recognized to be a prototype "scaffolding molecule" that collects binding partners and localizes them adjacent to the plasma membrane. Partners bound by filamin members include the small GTPases, RalA, Rac, Rho, and Cdc42, with RalA binding in a GTP-dependent manner; the exchange factors Trio and Toll; kinases such as PAK1; phosphatases; and transmembrane proteins. Most partner proteins are bound within the C-terminus portion of filamin.

Central to the structural organization of the resting platelet is an interaction between filamin and the cytoplasmic tail of the GPIbα subunit of the GPIb-IX-V complex.[26] The second rod domain (repeat 17) of filamin has a binding site for the cytoplasmic tail of GPIbα. The interaction between filamin A and GPIbα occurs at the atomic level. Repeat 17 of filamin A has a groove between certain β-sheet strands that forms a pocket for the GPIbα tail (see Fig. 123.10). Binding between filamin A and GPIbα is driven by entropic forces, and the alignment and specificity are provided by large residues that create a lock-and-key fit between the two molecules. The interaction between one filamin A subunit and GPIbα has an affinity of approximately 10 μM, whereas high-affinity binding (10 nM) occurs when each filamin A subunit in a molecule and both GPIbα chains in a vWF receptor are engaged. Studies have shown that the bulk of platelet filamin (>90%) is in complex with GPIbα. This interaction has three

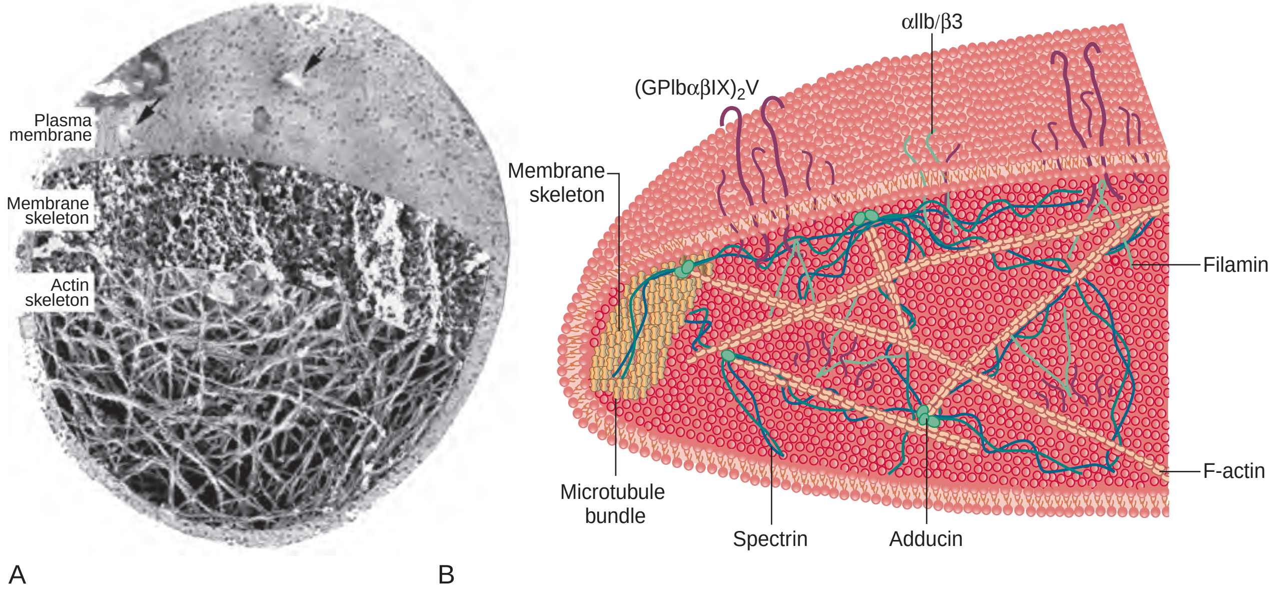

Figure 123.9 STRUCTURE OF THE RESTING HUMAN BLOOD PLATELET AND ITS ACTIN-BASED CYTOSKELETON. (A) Composite illustrating the major actin cytoskeletal layers of the resting platelet. *Plasma membrane*: The plasma membrane of the resting cell is flat and featureless, except for periodic invaginations that lead into the open canalicular system *(OCS) (arrows). Membrane skeleton*: The plasma membrane of the platelet is supported by a submembranous spectrin-based skeleton. This network is composed primarily of spectrin molecules, which are tetramers with actin binding sites at the ends. Actin filament ends dock on spectrin to complete the network. The association between spectrin and F actin is promoted by adducin. *Actin cytoskeleton*: As discussed earlier, the spectrin network is both directly and indirectly attached to the underlying actin filaments. Filament ends interconnect spectrin molecules, whereas the filamin links run from the filament sides to the plasma membrane receptor (GPIbαβIX)$_2$V. The cytoplasmic space has a dense filling of actin filaments. Actin filaments from the cell center radiate outward. As the filaments approach the plasma membrane, they turn and run in parallel with it. The actin filaments have been decorated using myosin subfragment 1 (S1), which gives them a twisted cable-like appearance in frozen samples. Myosin S1 labeling reveals the polarity of the actin filament. "Pointed" and "barbed" ends are definable. The ends of actin filaments are bound by the ends of spectrin molecules on the edges of the membrane network *(arrowhead)*. A microtubule coil composed of a single long microtubule resides just beneath the plasma membrane at the periphery of the thin axis of the platelet (not shown) (bar = 0.5 μm). (B) Schematic showing the structural features of the resting blood platelet cytoskeleton. Resting cells have discoid shapes. Structural elements that support this shape are (1) a marginal microtubule coil, (2) a spectrin-based membrane skeleton, and (3) a rigid network of cross-linked cytoplasmic actin filaments (only a small number of the actin filaments have been added to this illustration so that they will not obscure the rest of the structures in the cell). Platelets have a specialized membrane skeleton composed of spectrin, actin, and many associated proteins. Spectrin tetramers (200 nm long and 5 nm wide) have actin filament-binding sites at each molecular end. The membrane skeleton is held in compression between the plasma membrane and the cytoplasmic actin by filamin connections from the sides of actin filaments to the cytoplasmic tails of GPIbα subunit of the membrane glycoprotein complex that binds to von Willebrand factor (GPIbαβIX)$_2$V complex. Greater than 98% of the barbed ends of actin filaments are capped by adducin and capZ in the resting platelet.

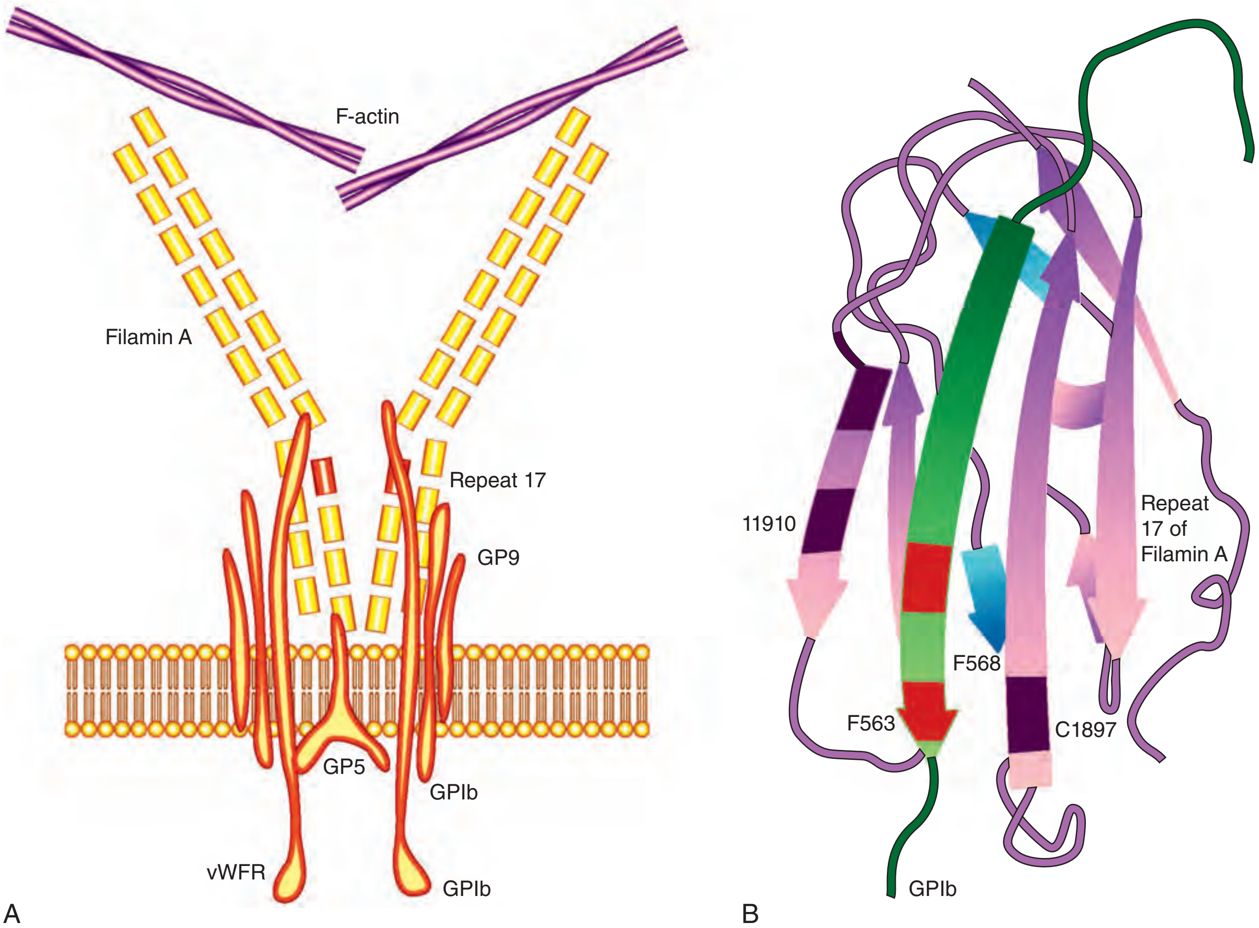

Figure 123.10 INTERACTION OF FILAMIN A WITH THE VON WILLEBRAND FACTOR RECEPTOR. (A) Model showing the orientation of filamin A when interacting with the GPIbα chain of the von Willebrand factor receptor (vWFR) and cytoplasmic actin filaments. For tight binding of filamin A to vWFR, both GPIbα chains of the receptor must be engaged by a single filamin A molecule. (B) Ribbon diagram showing the interface between filamin A repeat 17 and the filamin A binding region of the GPIbα tail (residues 556 to 577). Critical residues that provide the lock-and-key interaction between the two domains are indicated. *GP*, Glycoprotein.

consequences. First, it positions filamin's self-association domain and associated partner proteins at the plasma membrane while dangling filamin's actin binding sites into the cytoplasm. Second, because a large fraction of filamin is bound to actin, it aligns the GPIb-IX-V complexes on the surface of the platelet over the underlying filaments (see Fig. 123.9B). Third, because the filamin linkages between actin filaments and the GPIb-IX-V complex pass through the pores of the spectrin lattice, it restrains the molecular movement of the spectrin strands in this lattice and holds the lattice in compression. The filamin-GPIbα connection is essential for the formation and release of discoid platelets by megakaryocytes; platelets lacking this connection are large and fragile and are produced in low numbers. However, the role of the filamin-vWF receptor connection in platelet construction is unknown. Because a low number of Bernard-Soulier platelets form and release from megakaryocytes, it can be argued that this connection is a late event in the maturation process and is not required for platelet shedding. Both filamin and GPIbα are synthesized early, but linkage between the two may not occur until later, perhaps as late as the final stages of platelet shedding. Bernard-Soulier patients have an autosomal recessive bleeding disorder characterized by low platelet count with giant platelets, underscoring the importance of the filamin-GPIbα connection in stabilizing the membrane skeleton in platelet biology.

Aside from the erythrocyte, the platelet is the only cell whose membrane skeleton has been visualized at high resolution. Like the erythrocyte, the platelet membrane skeleton is a self-assembly of elongated spectrin strands (see Fig. 123.9) that interconnect through binding to actin filaments. Platelets express approximately 2000 spectrin molecules. Although considerably less is known about how the spectrin-actin network forms and is connected to the plasma membrane in the platelet relative to the erythrocyte, certain differences between the two membrane skeletons have been identified. First, the spectrin strands composing the platelet membrane skeleton interconnect using the ends of long actin filaments instead of short actin oligomers. These ends arrive at the plasma membrane originating from filaments in the cytoplasm. Hence the spectrin lattice is assembled into a continuous network by its association with actin filaments. Second, tropomodulins are not expressed at sufficiently high levels, if at all, to have a major role in capping the pointed ends of the platelet actin filaments. Instead, biochemical experiments have revealed that a substantial number (≈2000) of these ends are free in the resting platelet. Third, although little tropomodulin protein is expressed, α adducin and γ adducin are abundantly expressed and appear to cap many of the barbed ends of the filaments composing the resting actin cytoskeleton. Adducin is a key component of the membrane skeleton, forming a triad complex with spectrin and actin. Capping of barbed filament ends by adducin also serves the function of targeting them to the spectrin-based membrane skeleton because the affinity of spectrin for adducin-actin complexes is greater than for either actin or adducin alone. Platelet GPs involved in attaching spectrin to the membrane remain to be defined.

CHAPTER 124

MOLECULAR BASIS OF PLATELET FUNCTION

Margaret L. Rand and Sara J. Israels

A primary physiological role of platelets is to support hemostasis at sites of vascular injury by forming a plug that arrests blood loss (Fig. 124.1). Normally, disc-shaped platelets circulate in the bloodstream without adhering to the endothelium of the vessel wall. When the endothelium is damaged, platelets adhere to the exposed subendothelial collagen and, at high shear, to collagen-immobilized von Willebrand factor (VWF). Platelet adhesion at the site of vessel wall damage initiates activation events via intracellular signaling pathways that trigger (1) reorganization of the actin cytoskeleton that results in a shape change from discs to irregular spheres with filopodia, and enables platelet spreading to increase surface contact; (2) secretion of dense granule and α-granule contents, including adenosine 5-diphosphate (ADP) from the dense granules; (3) formation and release of second messengers including thromboxane A_2 (TxA_2); and (4) exposure of phosphatidylserine (PS) on the platelet surface, thereby creating a procoagulant activated platelet surface for assembly of coagulation factor complexes that accelerate the generation of thrombin (see Chapters 121 and 125). Platelet agonists, including ADP, TxA_2, and thrombin, bind to their specific membrane receptors, initiating signaling pathways that convert integrin αIIbβ3 from a low-affinity resting state to a high-affinity activated state capable of binding its ligands. Divalent fibrinogen and multivalent VWF function as bridges between αIIbβ3 on adjacent activated platelets, resulting in aggregation and plug formation. This series of platelet responses is essential for the hemostatic function of platelets, and when impaired by congenital or acquired defects, bleeding can occur. However, if these same events take place on a ruptured atherosclerotic plaque, they can lead to the formation of a platelet-rich thrombus that can occlude the arterial lumen and lead to ischemia (see Chapter 121).

This chapter addresses the molecular basis of platelet activation and primary hemostatic plug formation. Significant progress has been made in defining the molecular mechanisms that govern platelet responses, facilitated by the study of patients with congenital defects of platelet function and/or number, and by the study of genetically modified animals. The field of platelet biology has been expanding to encompass the roles of platelets in non-hemostatic processes; these are reviewed briefly at the end of this chapter (see section on Platelets Beyond Hemostasis), and some are touched upon throughout the chapter. What we have learned about the molecular mechanisms of platelets in the setting of hemostasis and thrombosis is now being applied in new areas to address new questions.

MOLECULAR BASIS OF PLATELET ADHESION

Substrates for Platelet Attachment and Spreading

Platelet plug formation is initiated by contact of circulating platelets with proteins in the subendothelial extracellular matrix (ECM). Normal endothelium maintains an effective barrier that prevents circulating platelets from contact with these ECM proteins (see Chapter 122). In addition to the physical barrier, endothelial cells actively inhibit platelet activation by the release of nitric oxide, prostacyclin, and enzymes (CD39/CD73) involved in the metabolism of ADP.[1] At sites of vascular injury, where endothelium is lost or damaged and the ECM becomes exposed to flowing blood, platelets come into close contact with ECM adhesive proteins that promote initial attachment and subsequent activation.

The subendothelial matrix can be viewed as a dynamic and mutable interface that provides multiple substrates to support platelet adhesion (Table 124.1). These substrates include collagens,[2] immobilized VWF,[3] fibronectin,[4] laminin,[5] and thrombospondin-1.[6] Plasma proteins such as fibrinogen,[7] vitronectin,[8] and circulating VWF also interact with platelets after binding to matrix components. The roles of collagen and VWF are well defined, while the contributions of other adhesive proteins to the initial attachment of platelets are less well established. Studies of mice deficient in individual matrix proteins have been useful in determining the contribution of these proteins to the integrated function of the ECM in the formation, growth, and stabilization of the platelet plug.

Shear rates in flowing blood, which vary depending on vessel caliber, influence the contribution of specific matrix proteins. At low shear, platelets can be captured directly by collagens, but at higher shear rates ($>1000\,s^{-1}$), VWF becomes critical in ensuring efficient platelet attachment via the receptor glycoprotein (GP)Ibα (Fig. 124.2A) (see section on Platelet Adhesion Receptors). VWF, secreted from endothelial cells and recruited from plasma, binds to type VI collagen in the vascular matrix via the VWF A1 domain, and to types I and III collagen in both superficial and deeper layers of the matrix via the VWF A3 domain (see Chapter 133).[9]

Collagen types I, III, and VI exposed at sites of vascular injury are key substrates for direct platelet adhesion. Collagen is a fibrillar protein made up of tropocollagen monomers packed into units of five to generate microfibrils.[10] Collagens have motifs that are not only recognized by VWF but also by the platelet collagen receptors α2β1 and GPVI (see section on Platelet Adhesion Receptors).[2,11] At low shear, collagen can function independently of VWF to capture platelets at the matrix surface. However, under high shear, collagen and VWF, with their respective receptors, function in concert.[9,12]

Platelet adhesion is supported by other substrates in the matrix, and by plasma proteins that interact with the matrix. It is likely that these proteins fine-tune the primary hemostatic response depending on the site or severity of the injury. Plasma proteins including fibronectin,[4,13] vitronectin,[8] and fibrinogen (and its polymerized product fibrin), matrix protein laminin[5] and platelet α-granule protein thrombospondin-1[6] support platelet adhesion in experimental systems. It is likely that most of these proteins play an ancillary role in vivo via mechanisms that include enhancing VWF immobilization in the matrix (laminin), protecting large VWF multimers from degradation (thrombospondin-1), or bridging between platelet receptors and matrix collagen (fibronectin).

Platelet Adhesion Receptors

Nomenclature

The individual adhesive proteins serve as ligands for specific receptors on the platelet surface (see Table 124.1). Several nomenclature systems have been used to identify the membrane glycoproteins of the platelet, such that the same receptor may have multiple designations. The original and still widely used system designates the membrane glycoproteins according to their electrophoretic mobility upon sodium dodecyl sulfate polyacrylamide gel electrophoresis; protein separation is based on molecular weight, with lower molecular-weight proteins having a greater mobility than those with higher molecular

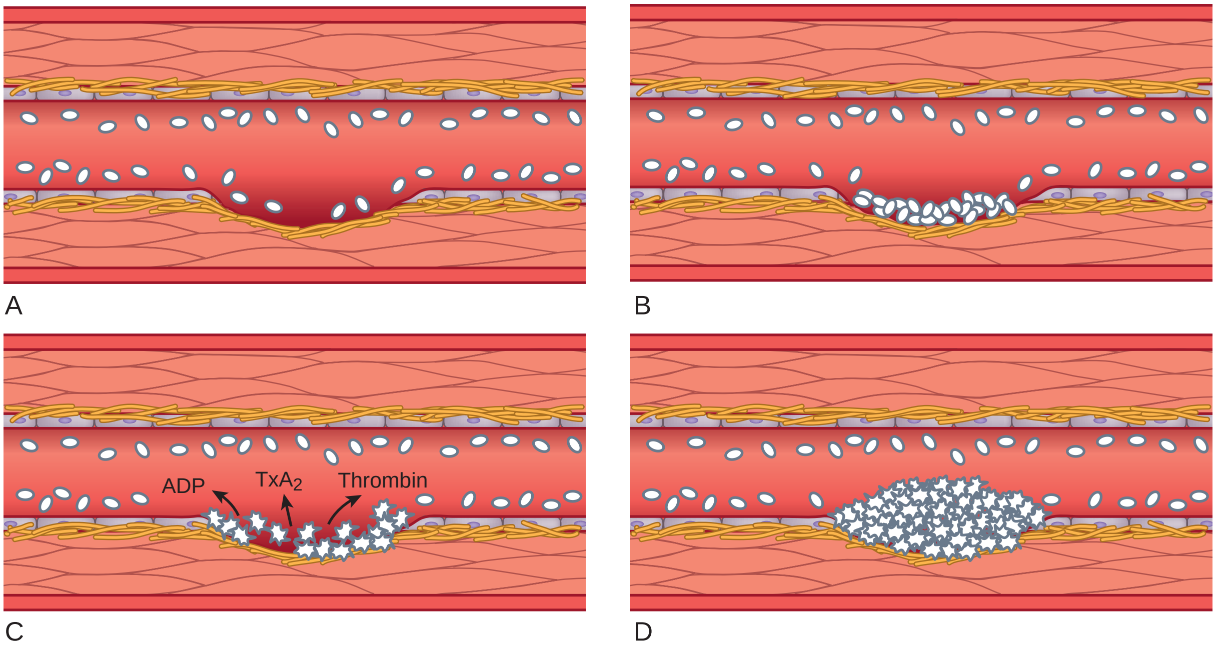

Figure 124.1 HEMOSTATIC RESPONSE OF PLATELETS TO VESSEL WALL INJURY. (A) Disruption of the endothelial cell lining of the blood vessel exposes constituents of the subendothelial extracellular matrix. (B) Platelets adhere to and spread on matrix constituents. (C) Activated platelets secrete ADP, synthesize and release thromboxane A_2 (TxA_2), and promote the generation of thrombin. (D) ADP, TxA_2, and thrombin activate and recruit additional platelets that aggregate to form a platelet plug.

TABLE 124.1 **Subendothelial Matrix Adhesive Proteins and Their Platelet Receptors**

Adhesive Protein	Receptor(s)
Collagen	GPIa–IIa (α2β1)[a] GPVI
von Willebrand factor	GPIb–IX–V GIIb–IIIa (αIIbβ3)
Fibronectin	GPIc–IIa (α5β1) GPIIb–IIIa (αIIbβ3)
Thrombospondin-1	αvβ3
Vitronectin	αvβ3 GPIIb–IIIa (αIIbβ3)
Laminin	α6β1

[a] Alternative name for receptor is given in brackets.

weight. Glycoproteins were designated as GPI, II, III, and so on, with GPI having the highest molecular weight. With greater resolution techniques, additional glycoproteins were identified, hence the subdivision designations, for example, GPIa, GPIb, GPIc; GPIIa, GPIIb. Many of the membrane glycoproteins on the platelet surface exist as noncovalent complexes, for example, GPIa–IIa, GPIb–IX–V, GPIIb–IIIa.

In addition to the GP nomenclature system, the αβ integrin nomenclature system is used. Several of the platelet membrane glycoproteins are members of the integrin family of adhesion receptors (see below), for example, GPIa–IIa is α2β1, GPIIb–IIIa is αIIbβ3. Some glycoproteins also have cluster of differentiation (CD) designations, for example, CD41 for GPIIb and CD61 for GPIIIa. Finally, some receptors have been named based on their function (e.g., the fibrinogen, fibronectin, and vitronectin receptors). Although functional designations can be appropriate from a descriptive standpoint, at least two different membrane glycoproteins on platelets serve as receptors for vitronectin and fibronectin (see Table 124.1), and several are receptors for collagen (see below). Beyond creating nomenclature complexity, redundancy of platelet receptors endows the platelet with the capacity to form multiple contacts with a single matrix constituent. Thus, a single ligand may initiate several distinct functional responses by engaging different receptors.

The Integrin Family of Adhesion Receptors

Integrins are members of a superfamily of broadly distributed adhesion receptors that mediate cell-matrix and cell-cell interactions. They are composed of noncovalently associated α and β transmembrane polypeptide subunits with large extracellular domains and short cytoplasmic tails. Of the 18 known α subunits, platelets express five (α2, α5, α6, αIIb, αv), and of the eight known β subunits, platelets express two (β1, β3), with a total of five different platelet integrins. It is estimated that half of the surface area of an activated platelet is occupied by integrin receptors. Many of the glycoprotein receptors on platelets that mediate cell-matrix adhesion are members of the integrin family (see Table 124.1). α2β1 is a receptor for subendothelial collagen (see below); α5β1 for fibronectin; α6β1 for laminin; αIIbβ3 for fibrinogen, VWF, and fibronectin; and αvβ3 for vitronectin. Of the integrins expressed on blood cells, αIIbβ3 is the most narrowly distributed and is restricted predominantly to platelets and megakaryocytes. It not only plays a prominent role in platelet aggregation (see section on Molecular Basis of Platelet Aggregation), but in many other platelet responses, including e.g., the association of platelets with tumor cells, an interaction involved in tumor metastasis, and with a variety of microorganisms, interactions involved in infection.

Role of GPIb–IX–V in Platelet Adhesion

GPIb–IX–V is a notable example of a major cell surface molecule involved in platelet adhesion that is not a member of the integrin family. GPIb is composed of an α (heavy) chain and two β (light) chains; the α and β chains both span the platelet membrane and are linked by disulfide bonds.[14] GPIX and GPV are smaller single-chain transmembrane polypeptides that are noncovalently associated with GPIb, and all three subunits are members of the leucine-rich repeat protein superfamily. GPIb and GPIX are necessary for the expression of the complex on the platelet surface. The GPIbα-GPIbβ–IX–V complex has a stoichiometry of 1:2:1:1 and exists in high copy number on the platelet surface (25,000 to 35,000 molecules per platelet) with the N-terminus of GPIbα being the major ligand-binding subunit of the complex. Platelet activation and aging are associated with the shedding of glycocalicin, a large proteolytic N-terminal fragment of GPIbα that is cleaved by (mostly) ADAM17. The cytoplasmic tail of GPIbα binds to a number of molecules, including 14-3-3ζ and filamin A (that binds to actin filaments in the cytoskeleton) (see section on the Platelet Cytoskeleton) that are important for GPIb-IX-V-mediated signaling.[15]

GPIb–IX–V plays a major role in hemostasis and thrombosis as a receptor for immobilized VWF in the subendothelium. Plasma VWF does not normally interact with platelet GPIb–IX–V, but at the high shear rates that occur in the arterial microcirculation, a conformational change in VWF bound to subendothelial collagen exposes a GPIbα binding site in its A1 domain. Thus, GPIb–IX–V binds to subendothelial VWF; this interaction is reversible with fast on and off rates, which allows for translocation (rolling) of platelets on the surface of the subendothelium (see Fig. 124.2A).[9,12] A polymorphism in the GPIbα gene leads to variable numbers of tandem repeats in the macroglycopeptide region (sialomucin "stalk") of the protein between the ligand-binding region and the transmembrane domain. The length of this region, which is determined by the number of tandem 13-amino acid repeats (one to four), may have a role in regulating platelet adhesion to VWF. With GPIb-IX-V being a major mechanoreceptor on platelets, a pulling force exerted on GPIbα by VWF binding activates a mechanosensory domain close to the transmembrane domain, thereby resulting in intracellular signaling.[14]

In addition to serving as a receptor for VWF in the subendothelium, GPIb–IX–V is also the high-affinity receptor for the soluble agonist thrombin (see section on Soluble Agonist Receptors). Other adhesive ligands for GPIbα include the counter-receptors P-selectin (CD62P), expressed on activated platelets and endothelial cells, and leukocyte integrin Mac-1 (αMβ2), which is involved in the formation of platelet-leukocyte conjugates.[15]

Platelets from patients with Bernard-Soulier syndrome (BSS) lack GPIb–IX–V because of variants in the *GP1BA, GP1BB*, or *GP9* genes that prevent the expression of the complex on the platelet surface. Decreased expression of GPIb–IX–V impairs platelet adhesion to the subendothelium and results in a bleeding diathesis (see section on Molecular Basis of Inherited Platelet Disorders).

Collagen Receptors

Subendothelial collagen has long been recognized as an important initiator of platelet responses, serving as a substrate for platelet adhesion, which ultimately results in platelet aggregation. Three different receptors are involved in platelet responses to collagen: the GPIb–IX–V complex, which binds to collagen via VWF (see above), and GPVI and α2β1 (GPIa–IIa), which directly bind to collagen.

GPVI, with 3000 to 4000 copies per platelet, is a transmembrane protein member of the immunoglobulin superfamily, with two extracellular immunoglobulin domains. Its cytoplasmic domain contains a proline-rich sequence that binds to tyrosine kinases involved in platelet signaling (see section on Activation Pathways).[9,16] GPVI is noncovalently associated with the Fc receptor γ chain (FcRγ) dimer, which is required for GPVI surface expression and for GPVI signaling via immunoreceptor tyrosine-based activation motifs (ITAMs) in the FcRγ cytoplasmic tails. There is in vitro and in vivo evidence of shedding of GPVI from the surface of activated platelets by the action of ADAM10 and ADAM17. Fibrin has recently been described as an additional ligand for GPVI, adding to the scope of the role of this receptor in platelet adhesion.[17,18] Deficiencies of GPVI can be associated with a mild bleeding diathesis (see section on Genetic Basis of Inherited Platelet Function Disorders).

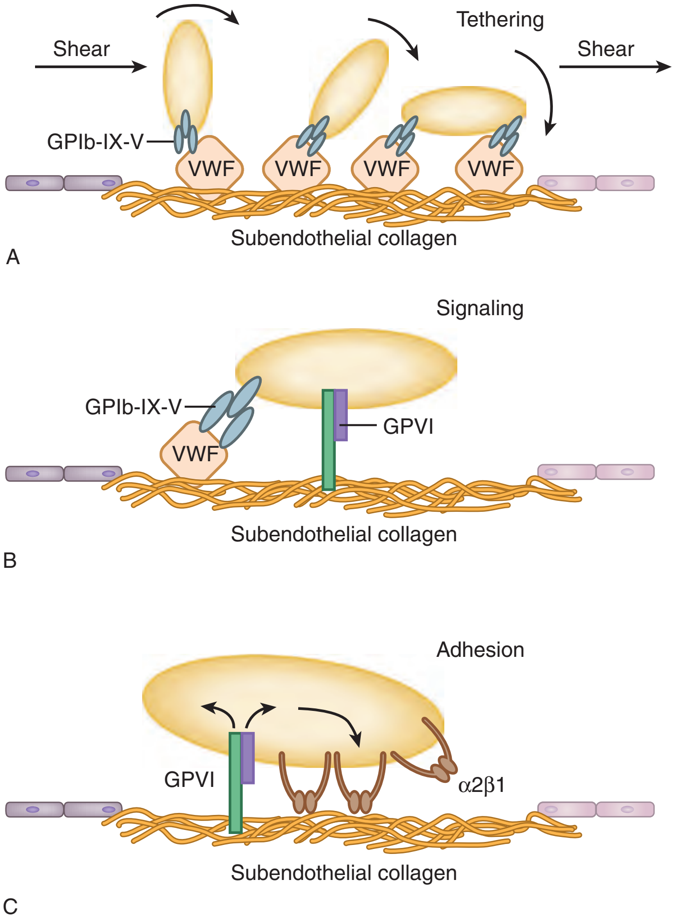

Figure 124.2 PLATELET ADHESION TO THE SUBENDOTHELIUM IS A MULTISTEP PROCESS. (A) Collagen-bound von Willebrand factor (VWF) in the subendothelium undergoes a conformational change when exposed to arterial shear stress such that glycoprotein (GP)Ibα of the GPIb–IX–V complex binds to the VWF A1 domain. These rapidly formed bonds are quickly broken and reestablished, causing platelet translocation, or rolling, along the subendothelium. (B) The translocation process slows platelet transit, allowing the signaling receptor GPVI to bind directly to collagen. (C) GPVI-mediated signal transduction pathways activate the integrin α2β1, enabling it to bind strongly to collagen. This final association between the platelet and collagen is stable, and allows the platelet to adhere firmly to the subendothelium.

α2β1, with approximately 4000 copies per platelet, is the major collagen-binding integrin on the platelet surface.[9,19] It undergoes a conformational change from a low- to a high-affinity state to allow it to bind to collagen. Silent polymorphisms in the α2 gene control its expression level, with higher plasma membrane levels associated with enhanced adhesion to collagen in vitro and an increased risk of cardiovascular disease.[20]

The adhesion of platelets to collagen is a complex, multistep process. An initial interaction of GPIb–IX–V with VWF in the subendothelium (see above) facilitates a direct, low-affinity interaction of GPVI with collagen (see Fig. 124.2B). Binding of GPVI to collagen is a potent stimulus to intracellular signaling pathways (see section on Activation Pathways). As a result of this signaling cascade, α2β 1 is activated to bind collagen with high affinity (see Fig. 124.2C), thereby forming a stable interaction. Alternatively, or in addition, low levels of constitutively activated α2β1 can initiate direct binding of platelets to collagen, thereby assisting GPVI to bind and to initiate activation signaling. At high shear, GPVI plays the major role in mediating stable adhesion, while at lower shear, α2β1 has a more significant role.[21,22]

CLEC-2

CLEC-2 (C-type lectin-like receptor 2) is a transmembrane glycoprotein that was originally described as the receptor responsible for platelet activation by the snake venom rhodocytin, inducing signaling events similar to those initiated by GPVI (see section on Activation Pathways).[16] The major endogenous ligand for CLEC-2 is the transmembrane mucin-like glycoprotein podoplanin, which is expressed on cells outside the vasculature[23]; the CLEC-2-podoplanin interaction does not appear to contribute to hemostasis and arterial thrombosis, although it is involved in inflammation-driven venous thrombosis. Critically, platelet CLEC-2 interaction with podoplanin on lymphatic endothelial cells regulates blood and lymphatic vascular separation during fetal development (see Chapter 122). The CLEC-2-podoplanin interaction on neuro-epithelium is important in blood vessel development in the embryonic brain.[16,24]

MOLECULAR BASIS OF PLATELET ACTIVATION

Soluble Agonist Receptors

Most agonist receptors on platelets are members of the superfamily of trimeric G protein-coupled receptors (GPCRs) that contain seven transmembrane spanning α-helices, four extracellular loops and domains, and four intracellular loops and domains. Upon binding of their ligands, intracellular signaling is initiated via G proteins (GTP-binding proteins) associated with the GPCRs at the inner plasma membrane, leading to diverse downstream responses (see section on Activation Pathways). The platelet GPCRs include receptors for thrombin, ADP, the arachidonic acid metabolite TxA_2, and epinephrine (Table 124.2).[25] Deficiencies or dysfunction of these GPCRs can result in bleeding diatheses ranging from mild to severe (see section on Molecular Basis of Inherited Platelet Disorders).

Thrombin Receptors

Thrombin receptors on platelets belong to the protease-activated receptor (PAR) family, GPCRs with a unique activation mechanism that involves cleavage of the N-terminal extracellular domain, thereby creating a new N-terminus that acts as a tethered ligand for the receptor. PAR1 and PAR4 are present on human platelets (PAR3 and PAR4 on mouse platelets); PAR1 is the high-affinity thrombin receptor (approximately 2500 copies per platelet), responding to thrombin at nanomolar concentrations, and PAR4 is a lower affinity receptor.[26] After thrombin cleavage of the N-terminus of PAR1, the tethered ligand (peptide sequence: Ser-Phe-Leu-Leu-Arg-Asn; SFLLRN) undergoes a conformational change and forms an intramolecular complex with a region also on the N-terminal extracellular domain of the receptor, referred to as ligand binding site-1. This triggers the G protein cycle of PAR1's associated G proteins. PAR4 is nonhomologous with PAR1 in both the peptide sequence of the tethered ligand (Gly-Tyr-Pro-Gly-Lys-Phe; GYPGKF) and its binding characteristics. Although PAR4 requires a higher concentration of thrombin for cleavage, once cleaved, it produces a more sustained signal than PAR1. GPIb–IX–V also possesses a high-affinity binding site for thrombin on GPIbα that facilitates PAR1 cleavage by thrombin.

Platelet PAR1 can be cleaved and activated by proteases other than thrombin, including several members of the membrane metalloproteinase family. These enzymes cleave PAR1 at sites different from the thrombin cleavage site, generating distinct tethered ligands, and distinct patterns of downstream G protein activation.[27]

ADP and ATP Receptors[28]

ADP is an important primary platelet agonist and amplifies other primary responses following its secretion from platelet dense granules.

TABLE 124.2 Platelet G Protein–Coupled Receptors, Their Associated G Proteins (A), and Their Effectors (B)

(A)

Agonist	GPCR	G Protein
Thrombin	PAR1	G_q, G_i (?), $G_{12/13}$

Platelets have two ADP receptors: P2Y1 and P2Y12, which are GPCRs that are coupled to distinct G proteins. ADP binding to P2Y1 (approximately 150 copies per platelet), which is coupled to the α subunits of G_q and $G_{12/13}$, mediates a transient rise in intracellular calcium, and induces platelet shape change and rapidly reversible aggregation. ADP binding to P2Y12 (approximately 500 copies per platelet), which is coupled to the α subunit of G_i, results in inhibition of adenylyl cyclase, decreased levels of cyclic AMP (cAMP) and enhancement of the aggregation and secretion responses produced by other agonists. The ADP-P2Y12 receptor axis is key to positive feedback signaling that recruits circulating platelets to the primary platelet plug. Full aggregation responses to ADP in vitro require concurrent activation of both receptor pathways.[29]

Adenosine 5'-triphosphate (ATP) is an antagonist of P2Y1 and P2Y12, but an activator of P2X1, a ligand-gated ion channel, that causes rapid influx of Ca^{2+} from the external milieu and amplifies responses to other agonists. The effects of ADP and ATP are modulated in vivo by CD39, a nucleoside triphosphate diphosphohydrolase (NTPDase-1) expressed by endothelial and vascular smooth muscle cells that hydrolyzes both ATP and ADP, thereby maintaining homeostasis and preventing inappropriate platelet activation.[1]

Thromboxane A_2 Receptor

In humans, the TxA_2 thromboxane/prostanoid (TP) receptor exists in two isoforms, the result of alternative splicing (TPα and TPβ). TPα is the dominant form expressed on platelets, with approximately 1000 copies per platelet.[30]

Epinephrine Receptor

Epinephrine is a relatively weak agonist but plays a role in potentiating platelet activation by other agonists, manifested through its ability to inhibit cAMP formation. In humans, the epinephrine receptor is the α_{2A}-adrenergic receptor (approximately 300 copies per platelet).

Activation Pathways

Once a subendothelial or soluble agonist binds to its receptor on the platelet surface, intracellular signaling pathways (detailed in Fig. 124.3) are set in motion. These signaling pathways result in reorganization of the cytoskeleton and platelet shape change, storage granule exocytosis, TxA_2 synthesis, PS surface exposure, and αIIbβ3 activation.

The signaling pathways, initiated by collagen binding to the ITAM-linked receptor GPVI, and by thrombin, ADP, TxA_2, and epinephrine binding to their specific GPCRs, comprise a "molecular toolkit"[31] of signaling molecules—effectors, second messengers, and signal integrators—which will be considered briefly. Much has been learned about the signaling pathways from genetically modified mice. The reader is referred to comprehensive reviews of platelet signaling for more detail.[15,24,31–42]

Heterotrimeric G Proteins Are Early Response Elements for Most Soluble Platelet Agonists[36]

The GPCRs for soluble platelet agonists are constitutively associated at the inner plasma membrane with specific heterotrimeric G proteins (consisting of α, β, and γ subunits) of the families G_q, $G_{12/13}$, and G_i (see Table 124.2A). The receptor for the potent platelet inhibitory molecule, prostaglandin I_2 (PGI_2; prostacyclin) is also a GPCR and is coupled to G_s.

In the basal, resting state, guanosine 5'-diphosphate (GDP) is bound to the α subunit of the G protein. Upon ligand binding, a GPCR acts as a guanine nucleotide exchange factor (GEF), promoting exchange of GDP for guanosine 5'-triphosphate (GTP) on different classes of the α subunit. Sites on the α and βγ subunits are thereby exposed, allowing for activation of effector molecules including the β isoform of phospholipase C (PLCβ), the γ isoform of phosphatidylinositol 3-kinase (PI3K), and the small GTPase (see below) Rho-specific GEF, p115-RhoGEF (see Table 124.2B). Adenylate cyclase is activated via G_s and inhibited by G_i. Intrinsic GTPase activity

of the α subunit, enhanced by GTPase-activating proteins (GAPs), specifically regulator of G-protein signaling (RGS) proteins,[43] hydrolyzes the α subunit-bound GTP to GDP, thus restoring the G protein to its inactive resting conformation.

Protein Tyrosine Kinases Activated by ITAM-linked Receptors Modulate Enzyme Activity and Allow for the Formation of Signaling Complexes[24,32,36]

GPVI is the most potent signaling collagen receptor. As an ITAM-linked receptor, clustering of GPVI upon binding to collagen results in phosphorylation of the constitutively associated FcRγ dimer by tyrosine kinases of the Src family (Fyn and Lyn) that are associated with the cytoplasmic domain of GPVI. Phosphorylation of tandem ITAM motifs enables binding of Syk via Src homology 2 (SH2) domains. Activation of the tyrosine kinase Syk leads to the phosphorylation of the adaptor protein LAT, which serves as the platform for the assembly of a signalosome—a complex of multiple signaling enzymes and adaptor molecules (e.g., SLP-76, Gads, Grb2) within membrane lipid rafts. The signalosome serves as a membrane scaffold for phosphorylation/activation of effectors including phospholipase Cγ (PLCγ) and the β isoform of PI3K.

The platelet receptor platelet-endothelial cell adhesion molecule (PECAM-)1 negatively regulates GPVI signaling via immunoreceptor tyrosine-based inhibitory motif (ITIM) sequences in its cytoplasmic tail by recruiting the tyrosine phosphatase SHP-2 and reducing LAT signalosome assembly.

The signaling pathway initiated by binding of GPIb–IX–V to VWF is similar to that of GPVI in that both involve activation of PLCγ via FcRγ, Fyn and Lyn, and Syk.[15,36] Binding of platelets to podoplanin via CLEC-2 also induces signaling events like those initiated through GPVI. However, rather than (tandem) ITAM phosphorylation, it involves phosphorylation of smaller hemITAMs in the cytoplasmic tails of dimerized receptors.

Phospholipase C Is Responsible for the Hydrolysis of Membrane PI-4,5P$_2$[36]

Activation of PLC, either the β-isoform (by thrombin, ADP, or TxA$_2$ via G$_q$) or the γ-isoform (by collagen, protein tyrosine kinases, and scaffold molecules) results in the hydrolysis of the inner plasma membrane leaflet phospholipid phosphatidylinositol-4,5-bisphosphate (PI-4,5P$_2$). The two second messengers that are the formed, soluble inositol-1,4,5-trisphosphate (IP$_3$) and membrane-associated diacylglycerol (DAG), lead, respectively, to increased cytosolic Ca^{2+} concentrations and to activation of a variety of proteins, most notably protein kinase C (PKC), a serine/threonine kinase.

Phosphatidylinositol 3-Kinase Forms 3-Phosphorylated Phosphoinositides[36,37]

Activation of PI3K isoforms, either γ (via G$_i$) or β (via the collagen signaling pathway), results in phosphorylation of PI-4,5P$_2$ to yield PI-3,4,5P$_3$. Inner membrane leaflet PIP$_3$ functions in signaling by interacting with proteins that contain binding motifs termed pleckstrin homology (PH) domains; an example of a major PIP$_3$ effector is Akt, that is activated to function as a serine/threonine kinase.

Serine/Threonine Kinases Regulate the Activity of Other Proteins Involved in Platelet Activation[33,36,44]

PKC is a central protein kinase in the PLC signaling pathway that phosphorylates the serine and threonine residues of many platelet proteins, including pleckstrin. Upon activation by DAG and Ca^{2+}, the conventional isoforms, PKCα and PKCβ, play important roles in platelet secretion and platelet spreading on fibrinogen, respectively. The serine/threonine kinase Akt (PKB) regulates platelet secretion and αIIbβ3 activation.

PKA and PKG are described in the section below on Cyclic Nucleotides.

The mitogen-activated PKs (MAPKs) ERK, JNK, and p38 are serine/threonine kinases that are activated following platelet stimulation with physiological agonists and are involved in platelet activation processes.[38]

Cytosolic Ca^{2+}[35,36,39]

An increase in the intracellular Ca^{2+} concentration ([Ca^{2+}]$_i$) is a key event that triggers platelet activation and aggregation; Ca^{2+}-dependent responses include shape change, secretion, procoagulant surface exposure, TxA$_2$ formation, and αIIbβ3 activation. The basal [Ca^{2+}]$_i$ is maintained at approximately 0.05 μM and can increase to greater than 1 μM with strong stimulation. The initial increase results from IP$_3$-mediated release of Ca^{2+} from the dense tubular system (DTS) via IP$_3$-receptors. Upon depletion of this Ca^{2+} pool, store-operated Ca^{2+} entry (SOCE) occurs from the platelet exterior. Stromal interaction molecule 1 (STIM1), a protein in the DTS membrane, undergoes a conformational change when DTS Ca^{2+} is depleted, allowing it to bind and activate Orai1 (calcium release-activated calcium channel protein 1), the major SOCE Ca^{2+}-selective release-activated Ca^{2+} (CRAC) channel in the platelet plasma membrane.

Phospholipase A$_2$ Is Responsible for the Synthesis of TxA$_2$[31]

An increase in [Ca^{2+}]$_i$ is one of the main triggers for activation of cytosolic phospholipase A$_2$ (cPLA2), resulting in the formation of the proaggregatory prostanoid TxA$_2$. cPLA2 hydrolyzes the polyunsaturated fatty acid arachidonic acid from the C2 position of inner plasma membrane leaflet phospholipids, and arachidonic acid is converted to the cyclic endoperoxide intermediates prostaglandin (PG) G$_2$ and PGH$_2$ by cyclooxygenase (COX)-1. Thromboxane synthase in the platelet cytosol metabolizes PGH$_2$ to TxA$_2$, which diffuses out of the platelet and is available to activate additional platelets via the TP receptor.

Small GTPases[40–42]

In contrast to the heterotrimeric G proteins associated with GPCRs, platelets also contain small (i.e., low molecular weight) GTPases (belonging to a superfamily of monomeric G proteins) that are critical signaling integrators. Like heterotrimeric G proteins, they are activated by GEFs and inactivated by GAPs. Roles of specific small GTPases of the Rho family, involved in cytoskeletal dynamics, the Ras family, involved in cell adhesion, and the Rab family, involved in membrane trafficking, are described below in the sections Cytoskeletal Reorganization, Molecular Mechanisms of Aggregation and Secretion of Granules, respectively.

Cyclic Nucleotides Are Inhibitory[36]

PGI$_2$ and nitric oxide (NO), synthesized by the endothelium, aid in maintaining platelets in a resting state. PGI$_2$-mediated activation of adenylate cyclase via G$_s$ increases the intracellular level of cAMP. Nitric oxide (NO) diffuses into the cytoplasm and activates soluble guanylate cyclase, generating cGMP. These cyclic nucleotides activate PKA and PKG, respectively. Both serine/threonine kinases phosphorylate multiple substrates including filamin and the small GTPase Rap1. Elevated levels of cAMP and cGMP result in sequestration of intracellular Ca^{2+} in the DTS, and inhibition of cytoskeletal rearrangement, granule secretion, and aggregation.

In contrast, lowered levels of cAMP occur due to inhibition of adenylate cyclase via G_i; this is important in facilitating activation of platelets.

Reorganization of the Actin Cytoskeleton

Platelet plug formation requires platelets to undergo a rapid change from their resting discoid shape to active forms that spread over the damaged subendothelium and recruit additional platelets by providing an expanded surface area for platelet–platelet or platelet–leukocyte interactions. The discoid shape of the circulating platelet is maintained by an internal cytoskeleton composed of polymers of actin and tubulin and their associated proteins (see also Chapter 123). Shape change requires the remodeling of the resting cytoskeleton and the assembly of new cytoskeletal fibers to transform the platelet into its activated configuration.

The Resting Platelet Cytoskeleton

The resting platelet cytoskeleton maintains cell shape and integrity as the platelet encounters the high shear forces of blood flow in small vessels. The spectrin-based membrane skeleton (similar but not identical to that of erythrocytes) forms a contiguous network with actin filaments to support platelet ultrastructure. Actin is the single most abundant platelet protein (2 million copies per platelet), forming 2000 to 5000 linear actin polymer filaments that are cross-linked to form a rigid cytoplasmic network. Cross-linking proteins include filamin A and B, and α-actinin. The interaction between filamin A/B and the cytoplasmic tail of the VWF receptor GPIbα provides structural stability and the major link between the plasma membrane and the actin cytoskeleton.[45] Loss of this linkage in platelets deficient in either GPIbα (BSS) or filamin A results in loss of restraint of the spectrin lattice, swelling of the membrane skeleton, and large fragile platelets that are subject to rapid clearance from the circulation.[12]

Platelets contain a long microtubule wound 8 to 12 times into a coil that sits just beneath the plasma membrane, maintaining the discoid shape of the resting platelet. Microtubules are rigid polymers made up of αβ-tubulin heterodimeric subunits.[46] β1-tubulin deficient mice have platelets that are spherical and fail to develop a discoid shape due to aberrant microtubule assembly.[47] A heterozygous human variant in β1-tubulin, which may be present in as many as 10% of the general population, results in decreased levels of β1-tubulin and a subset of spherocytic platelets.[48]

Cytoskeletal Reorganization During Platelet Activation

The assembly and disassembly of the actin cytoskeleton allows platelets to spread. Following platelet activation, the platelet makes contact with the ECM, initially changing shape from disc to sphere and developing filopodia, followed by flattening and spreading of broad lamellae.[49] Granules and organelles are relocated to the center of the cell. The filopodia are filled with long actin filaments originating in the center of the cell. Increases in $[Ca^{2+}]_i$ initiated by signaling through G_q result in activation of gelsolin, a multidomain protein with binding sites for Ca^{2+}, actin, and phospholipid. Ca^{2+} binding alters the conformation of gelsolin such that it binds and cleaves actin filaments, leading to disassembly of the resting actin cytoskeleton and allowing the platelet to change shape. Signaling via $G_{12/13}$ and p115-RhoGEF activates the small GTPase RhoA that is also involved in regulating actin filament formation and myosin contraction. For example, actin filaments are stabilized by the activation of Rho-activated kinase (p160ROCK) and LIM-kinase.

Assembly of the activated platelet cytoskeleton doubles the actin filament content of the platelet by exposing nucleation ends on existing actin filaments (the result of severing of filaments by gelsolin) or creating new nucleation sites (by the Arp 2/3 complex). The Arp2/3 complex is enriched in the periphery of the activated platelet where actin assembly is occurring, and the complex is activated by proteins associated with cell adhesion sites and by Wiskott-Aldrich syndrome protein (WASp) family members.[50]

Platelets are also the force-generating component of clot retraction. αIIbβ3 is tethered to underlying actin filaments in association with cytoplasmic proteins talin, filamin, paxillin, zyxin, α-actinin, and vinculin. Association of cytoplasmic myosin with actin provides the motor for the contractile force. Platelets contain nonmuscle myosin IIA and IIB; myosin II is a hexamer made up of two heavy chains and four light chains (myosin light chains: MLCs). Assembly into bipolar filaments is the result of Ca^{2+}-activated phosphorylation of the 20-kDa MLCs by MLC kinase, enhanced by blocking MLC dephosphorylation through Rho kinase. *MYH9*-related thrombocytopenia is the result of variants in the gene for nonmuscle myosin heavy chain IIA (NMMHC-IIA) (see section on Molecular Basis of Inherited Platelet Disorders).[51]

Secretion of Granules

Platelet activation leads to the release of more than 300 diverse molecules that stimulate or inhibit platelets or other blood and vascular cells, covalently modify the mechanical properties of thrombi, regulate coagulation, contribute to cell adhesive events, and modulate wound healing, inflammation, and angiogenesis (see Chapters 122 and 125).

Most of the substances that are actively and selectively secreted from platelets are packaged in storage granules formed in megakaryocytes. Platelets contain three types of granules: dense (δ) granules, α-granules, and lysosomal granules (Fig. 124.4A).

Dense Granules

Dense granules belong to the family of lysosome-related organelles (LROs) that also includes melanosomes, cytotoxic T-cell granules, and neutrophil azurophilic granules. Platelets contain three to eight dense granules, which store high concentrations of cations (Ca^{2+}, Mg^{2+}, K^+), polyphosphate, nucleotides (ADP, ATP, GTP), and bioactive amines (serotonin and histamine); they are innately dense when viewed by electron microscopy due to their Ca^{2+} content. These granules undergo a complex maturation process that is regulated by biogenesis of LRO complexes (BLOCs), involving the delivery of specialized cargo by Rab GTPases,[52] and the modulation of zinc transport by the transmembrane protein TMEM163.[53] Variants in specific protein members of BLOCs 1, 2, and 3, or in the adaptor protein complex 3 (AP3) result in dense granule deficiency and associated LRO abnormalities in mice and in Hermansky-Pudlak syndrome (HPS) 1 to 10 in humans, characterized by mucocutaneous bleeding and oculocutaneous albinism (see section on Molecular Basis of Inherited Platelet Function Disorders).[54]

α-Granules

α-Granules are unique to platelets and are the most abundant granule type: 50 to 80 granules per platelet, taking up 10% of the platelet volume. They contain a large number of proteins that are either synthesized by megakaryocytes or taken up from plasma by endocytosis.[55] Genetic defects in *NBEAL2* and *VPS33B*, genes involved in α-granule synthesis, result in α-granule deficiency syndromes (see section on Molecular Basis of Inherited Platelet Disorders).[56–60] Proteomic studies have identified more than 300 unique proteins released by α-granules.[61] These proteins have diverse functions and can be classified as coagulants and anticoagulants (e.g., factors V and XI, antithrombin,

Most of these are present on the resting platelet plasma membrane, but following exocytosis, there is a marked increase in plasma membrane expression of some receptors including αIIbβ3 and GPVI. Other receptors, such as P-selectin (CD62P), are only expressed on the plasma membrane after platelet activation and granule exocytosis.[60]

Lysosomal Granules

Platelets have small numbers of primary and secondary lysosomes that contain enzymes involved in degradation of proteins, carbohydrates, and lipids. These enzymes include cathepsins, elastase, collagenases, galactosidase, glucuronidase, and acid phosphatase.

Mechanism of Granule Secretion

The secretion of platelet granule contents occurs through mechanisms analogous to those required for the exocytosis of granules from neurons and mast cells. The process is complex, and both the rate and extent of secretion are related to the strength of the activating stimulus: triggered rapidly and completely by strong agonists such as thrombin. Induction of secretion by weak agonists (e.g., ADP) occurs when the cells are brought into close contact, such as during aggregation,[64] and is dependent on TxA$_2$ to amplify the effect of the primary agonist. Dense granule release is the most rapid; lysosomal release is the slowest; α-granule release is the most variable. The bioactive molecules in the releasate affect the microenvironment of the platelet plug contributing to hemostasis and would healing.

In most cells, exocytosis occurs when vesicles fuse with the plasma membrane and release their contents into the extracellular milieu. In platelets, granules clustered centrally by platelet shape change also fuse with one another and with the open canalicular system (OCS), a system of invaginations of the plasma membrane extending into the interior of the platelet; the granule contents diffuse to the external environment. Membrane fusion is driven by the soluble *N*-ethylmaleimide–sensitive factor (NSF) attachment protein receptors (SNAREs). Platelets have the three basic components of SNARE machinery: tSNAREs (target receptors associated with OCS and plasma membrane), vSNAREs (vesicle-associated receptors associated with the granule membranes), and soluble regulators (including NSF and NSF-attachment proteins).[62,65] vSNAREs including vesicle-associated membrane proteins (VAMP2, VAMP3, VAMP7, VAMP8) interact with syntaxin isoforms (syntaxin 8, syntaxin 11) and synaptosomal-associated protein (SNAP)-23 on the target membranes to form four helix bundles that bring the vesicular and target membranes into proximity (see Fig. 124.4B). SNARE function is tightly regulated by chaperone proteins. NSF regulates membrane interaction by disassembling SNARE complexes on the same membrane so that they are available to form complexes with proteins on opposing membranes. The Sec1/Munc proteins (Munc18a, b, and c, and Munc13-4) and the small GTPase Rab 27 regulate granule docking,[65] a preliminary step to granule membrane fusion (see Fig. 124.4B). Conditional

(2) Docking: the engagement of vSNAREs on the granule membrane and tSNAREs on the target membrane to form a pre-fusion complex. In platelets, these docking proteins include VAMPS (represented by VAMP8) on α-granule and dense granule membranes, STX11/SNAP-23 complex on the plasma membrane and accessory proteins Munc13-4 and Munc18b/Munc18-2. (3) Fusion/secretion: involves the zippering of opposing SNAREs, applying force to fuse the granule and plasma membranes, resulting in release of the granule contents. Additional mediators of this active process include Rab GTPases, PKC, pleckstrin, Ca^{2+}, and NSF. *CXCL*, CXC-chemokine ligand; *EGF*, epidermal growth factor; *GP*, glycoprotein; *IgG*, immunoglobulin G; *NSF*, *N*-ethylmaleimide-sensitive factor; *PAI-1*, plasminogen activator inhibitor-1; *PDGF*, platelet-derived growth factor; *PF4*, platelet factor 4; *PKC*, protein kinase C; *RANTES*, regulated upon activation, normal T-cell expressed, and secreted; *SNAP-23*, synaptosomal-associated protein-23; *SNARE*, soluble *N*-ethylmaleimide–sensitive factor attachment protein receptor; *STX11*, syntaxin 11; *TGF-β*, transforming growth factor-β; *tSNARE*, target SNARE; *VAMP8*, vesicle-associated membrane protein 8; *VEGF*, vascular endothelial growth factor; *vSNARE*, vesicle-associated SNARE; *VWF*, von Willebrand factor; *β-TG*, β-thromboglobulin.

knock-out studies in mice have demonstrated the contributions of vSNAREs and SNAP-23 to platelet secretion, bleeding and thrombosis.[66,67]

Activation pathways involving intracellular Ca^{2+}, Rab GTPase, and PKC isoforms regulate the SNARE complex interactions. PKC isoforms phosphorylate several of the SNARE proteins and their regulators, including Munc18c, syntaxin 4, and SNAP-23. The PKC substrate pleckstrin is also a critical mediator of granule exocytosis: pleckstrin-deficient mice exhibit markedly impaired platelet secretion.[68]

The important role of granule releasates in hemostasis is highlighted by the bleeding diathesis that occurs with granule deficiencies or defects of granule exocytosis. α-Granules secrete fibrinogen and VWF, which mediate platelet-platelet and platelet-ECM interactions. Of the total VWF, 20% is contained in α-granules, enriched in the most potent high-molecular-weight VWF multimers (see Chapter 132). ADP released from dense granules is essential for recruitment of circulating platelets to the primary hemostatic plug. Other mediators released from α-granules play key roles in additional functions including wound repair, angiogenesis, and host defense. However, these modulators can also be pathogenic, contributing to the inflammatory response, atherosclerosis, and tumor metastases (see Fig. 124.4A) (see section below on Platelets Beyond Hemostasis).[69]

Procoagulant Surface Exposure

The phospholipids of the plasma membrane of resting platelets are asymmetrically distributed between the leaflets of the membrane bilayer, with choline-containing phospholipids predominating in the outer cytoplasmic leaflet, and the minor anionic aminophospholipid PS predominating in the inner. Platelet adhesion to collagen and stimulation with thrombin synergistically result in a loss of the asymmetry, or "scrambling," of the membrane phospholipids, such that PS becomes exposed on the external plasma membrane leaflet.[70] PS translocated to the surface of activated platelets facilitates the assembly of the intrinsic tenase complex (factors VIIIa, IXa, and X) and prothrombinase complex (factors Va and Xa, and prothrombin), contributing to the burst of thrombin generation that occurs in the propagation phase of coagulation (see Chapter 125). It sustains the procoagulant response by concentrating the coagulation factors and protecting them from inactivation.[71] Specifically, the negatively charged γ-carboxyglutamate (Gla) residues of the vitamin K-dependent factors, factors VII(a), IX(a), X(a), and prothrombin, mediate Ca^{2+}-dependent binding of these factors to negatively-charged PS. There is recent evidence that plasminogen also binds to PS-exposing platelets, thereby linking coagulation and fibrinolysis.[72]

Exposure of PS on the platelet surface requires sustained increases in $[Ca^{2+}]_i$ via influx across the plasma membrane and activation of phospholipid scramblase (see Fig. 124.3), which rapidly and nonspecifically transports phospholipids between the membrane leaflets.[39,73] The transmembrane protein TMEM16F (anoctamin 6) has been shown to be essential for PS exposure,[74] but its specific role is not yet clear. Scott syndrome, a platelet disorder characterized by a defect in PS exposure, is associated with variants in *TMEM16F* (*ANO6*; see section on Molecular Basis of Inherited Platelet Disorders).[75] There is heterogeneity in the platelet response to stimulation: only a proportion of activated platelets expose PS (this population of platelets is variously described as being procoagulant, super-activated, coated [with covalently linked platelet secretion products (e.g., serotonin, fibrinogen, factor Va)], capped or having Sustained Calcium-Induced Platelet [SCIP] morphology). Besides supporting thrombin generation, PS-exposing platelets are characterized by inactive αIIbβ 3 and a distinct balloon-like morphology with loss of internal organelles. In vitro, they are readily identified by annexin A5 or lactadherin binding. The pathway that leads to rapid PS exposure on activated platelets can be distinguished from a slower intrinsic apoptotic pathway, which involves caspase activation.[73]

Platelet-Derived Extracellular Vesicles

PS exposure is accompanied by blebbing of extracellular vesicles (microparticles; microvesicles; ectosomes) from the plasma membrane[76]; Scott syndrome platelets are deficient in extracellular vesicle formation. These small (0.05 to 1 µm diameter) vesicles are distinct from exosomes, which are released from intracellular vesicles. Circulating extracellular vesicles are thought to originate from megakaryocytes as well as from platelets. The surface membranes of extracellular vesicles are heterogeneous in the expression of platelet membrane receptors such as αIIbβ3 and GPIb–IX–V, and activation markers such as CD62P, CD63, activated αIIbβ3, and surface-exposed PS. Extracellular vesicles can support hemostasis; platelets from patients with the very rare bleeding disorder Castaman syndrome have an isolated deficiency of extracellular vesicle generation. Increased circulating levels of extracellular vesicles have been reported in thrombotic conditions (such as myocardial infarction, thrombotic thrombocytopenic purpura, sickle cell disease, and diabetes), immune-mediated conditions (such as immune thrombocytopenia and heparin-induced thrombocytopenia), and in malignancy and inflammatory conditions. Whether they are active contributors or passive indicators of these conditions is uncertain.[76] Extracellular vesicles also play a role in platelet-cell communications, delivering bioactive molecules (e.g., cytokines, eicosanoids, RNA species) to target cells, even those inaccessible to platelets, as they can enter lymph, bone marrow and synovial fluid.[77] For example, extracellular vesicles formed by platelets activated via GPVI have been shown to contribute to the pathophysiology of rheumatoid arthritis, delivering IL-1 to synovial fibroblasts.

MOLECULAR BASIS OF PLATELET AGGREGATION

αIIbβ3 and Molecular Mechanisms of Aggregation

Integrin αIIbβ3 is the most abundant membrane protein on the platelet surface, with 40,000 to 80,000 copies per resting platelet, a very high receptor density for such a small cell. Platelet activation can produce an additional 10% increase in this number as a result of expression from internal pools, namely, α-granule membranes. On resting platelets, αIIbβ3 is in a low affinity bent conformation that is unable to bind its ligands. Activation of αIIbβ3 results in a change to a high affinity, extended conformation (Fig. 124.5), allowing it to bind divalent fibrinogen or multivalent VWF, which can bridge to other activated αIIbβ3 molecules on adjacent platelets, mediating platelet aggregation. The (extracellular) N-terminal portion of β3 contains three divalent cation-binding sites including the metal-ion dependent adhesion site (MIDAS); metal ions (Ca^{2+}) are required for ligand binding to αIIbβ3. Absence or dysfunction of αIIbβ3 on the platelet surface leads to Glanzmann thrombasthenia (GT), a disorder characterized by a moderate-to-severe bleeding diathesis and absent in vitro platelet aggregation responses to all agonists (see section on Molecular Basis of Inherited Platelet Disorders).

Activation of platelets with any of the agonists described in the preceding sections, including collagen, thrombin, ADP, and TxA_2, results in the conversion of αIIbβ3 from its resting to its activated state.[78] This transformation is a consequence of the intracellular signaling pathways set in motion when the agonist binds to its receptor (see section on Activation Pathways), leading to the final common pathway that results in aggregation; it occurs rapidly, on the order of seconds, after platelet exposure to an agonist. The signal is transmitted to the cytoplasmic tails of αIIbβ3 and through the transmembrane helices, ultimately inducing a change in the extracellular domain to render αIIbβ3 competent to bind its ligands. The signaling process responsible for this transformation is referred to as "inside-out" signaling through αIIbβ3.

Specifically, it is the agonist-induced increase in $[Ca^{2+}]_i$ and DAG formation that result in the final common pathway of integrin activation.[79] Via the Ca^{2+}- and DAG-regulated GEF CalDAG-GEFI, the small GTPase Rap1 (of the Ras family) is activated and promotes binding of the cytoskeletal protein talin to the cytoplasmic domain of β3.[80] Talin cooperates with kindlin-3, which also binds to the cytoplasmic domain of β3, to unclasp the complex between the αIIb and β3 cytoplasmic tails. This leads to a dissociation of the transmembrane complex of the αIIb and β3 subunits, inducing a conformational change in the extracellular domains. The bent conformation of αIIbβ3 is transitioned through intermediate configurations to an extended conformation that exposes the ligand-binding site (see Fig. 124.5) for fibrinogen and VWF.

Both fibrinogen and VWF bind to extracellular domains of activated αIIbβ3 via Arg-Gly-Asp (RGD) sequences. Fibrinogen contains two such sequences, RGD-Ser and RGD-Phe, in its Aα chains, and VWF contains one in its C1 domain. The RGD sequence is a broadly used recognition code in cellular adhesive reactions; it is found on a variety of proteins, and it is recognized by several other integrin receptors. Fibrinogen has a second binding sequence for activated αIIbβ3, Lys-Gln-Ala-Gly-Asp-Val (KQAGDV), in the C-terminus of its γ-chains, that is the primary one by which fibrinogen binds to activated αIIbβ3.[79] While fibrinogen binding mediates platelet aggregation at low shear, it is VWF binding that mediates aggregation at high shear.[81] Other ligands that bind αIIbβ3, mainly via an RGD sequence, include fibronectin, vitronectin, and thrombospondin-1.

αIIbβ3 transmits signaling information bidirectionally in that ligand binding induces further conformational changes to activated αIIbβ3; these result in exposure of binding sites on the cytoplasmic tails of the integrin for cytoskeletal and signaling proteins, and activation of protein kinases and phosphatases. This "outside-in" signaling is important in platelet responses such as full platelet spreading, irreversible aggregation, and clot stability and retraction.[82]

The close platelet-platelet contact brought about by aggregation facilitates binding of additional cell surface ligands on one platelet to cell surface receptors on adjacent platelets. Such binding can affect platelet activation and thrombus stability via initiation of intracellular signaling or formation of additional contacts between platelets. These ligand/receptor pairs include: ephrin/Eph kinases; semaphorin4D/CD72 and a member of the plexin B family; and growth-arrest specific gene 6 (Gas-6)/receptor tyrosine kinases Tyro3, Axl, and Mer.[31,81,83]

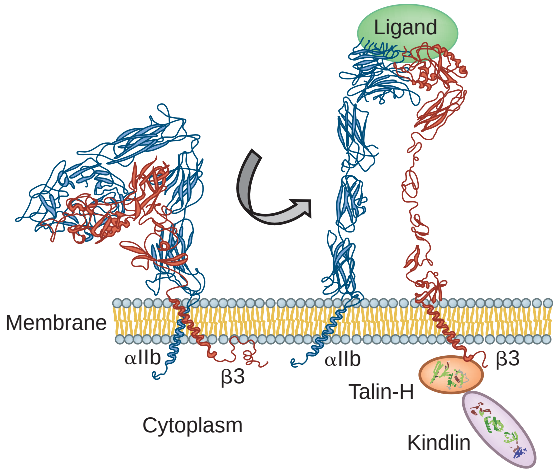

Figure 124.5 MODEL SHOWING THE ACTIVATION OF αIIbβ3. Signaling pathways induced by platelet agonists result in talin and kindlin binding to the cytoplasmic tail of β3 and inside-out signaling such that the integrin is transformed from its low-affinity bent conformation on the resting platelet to its high-affinity extended conformation on the activated platelet. The extended conformation has the ligand binding site exposed, allowing for the binding of fibrinogen or von Willebrand factor, and thus for platelet aggregation. Binding of these ligands initiates outside-in signaling, triggering further intracellular signal transduction and platelet responses. This model is based on the crystal structure of the extracellular domain of αvβ3, and the cytoplasmic tails on the nuclear magnetic resonance structure of αIIbβ3. *(Adapted, with permission, from Bledzka K, Smyth SS, Plow EF. Integrin αIIbβ3. From discovery to efficacious therapeutic target. Circ Res. 2013;112:1189.)*

Laboratory Evaluation of Aggregation

The in vitro aggregation response of platelets is most commonly assessed using aggregometry, considered to be the gold standard of platelet function testing.[84] In the aggregometer, platelet responses are measured in suspension, bypassing the initial adhesion response of platelets to the subendothelial ECM that occurs in vivo (see section on Platelet Adhesion). Optical or turbidometric aggregometry, now more often referred to as *light transmission aggregometry (LTA)*, was developed in the 1960s; in LTA, light transmission through a rapidly stirred suspension of platelets at 37°C is recorded upon addition of a soluble agonist (Table 124.3). With all agonists except epinephrine, there is an initial, transient, small decrease in light transmission from baseline due to actin cytoskeleton reorganization and platelet shape change from discs to more rounded forms with extended filipodia. This is followed by a larger increase in light transmission as the platelets aggregate. Depending on the agonist and its concentration, platelets may deaggregate, indicated by a subsequent decrease in light transmission (Fig. 124.6).

In clinical laboratories, platelet-rich plasma (PRP), obtained by low-speed centrifugation of a whole blood specimen anticoagulated

TABLE 124.3 **Agonists Used in the Laboratory Evaluation of Aggregation**

Agonist	In Vivo/In Vitro Mechanism of Action
Thrombin receptor-activating peptide (TRAP)[a]	SFLLRN (Ser-Phe-Leu-Leu-Arg-Asn), the peptide sequence of the new N-terminus of PAR-1 after thrombin cleavage (binds to (uncleaved) PAR-1 in vitro)
ADP	Released from platelet dense granules; acts synergistically with many other agonists (binds to P2Y1 and P2Y12)
Arachidonic acid	Is metabolized by the cyclooxygenase pathway to TxA_2 which is released from stimulated platelets and is rapidly metabolized to inactive TxB_2 in plasma (TxA_2 binds to TP)
U46619	Stable TxA_2 mimetic (binds to TP)
Collagen	In subendothelial extracellular matrix (binds to GPVI and α2β1)
Epinephrine[b]	A weak agonist that is not associated with platelet shape change and that potentiates other agonists; may allow for hormonal regulation of hemostasis (binds to α_{2A}-adrenergic receptor)
Ca^{2+}-ionophore	Directly mobilizes intracellular Ca^{2+} (does not bind to a receptor)
Ristocetin[c]	An antibiotic that changes the conformation of VWF, exposing the binding site for GPIbα of the GPIb–IX–V complex, allowing platelet agglutination by VWF

GP, Glycoprotein; *PAR*, protease-activated receptor; *TP*, thromboxane/prostanoid; *TxA_2*, thromboxane A_2; *TxB_2*, thromboxane B_2; *VWF*, von Willebrand factor.

[a] TRAP is used as a substitute for thrombin. Thrombin binds to GPIb–IX–V and cleaves PAR-1 and PAR-4, but is not often used in the assessment of platelet aggregation in citrated platelet-rich plasma as it causes fibrin clot formation.

[b] Low response to epinephrine occurs in a proportion of healthy individuals due to natural variation in receptor density, and is not necessarily indicative of a platelet function disorder.

[c] In contrast with the other agonists that stimulate aggregation, an energy-requiring process, ristocetin induces platelet agglutination via VWF, a process that does not require platelets to be metabolically active.

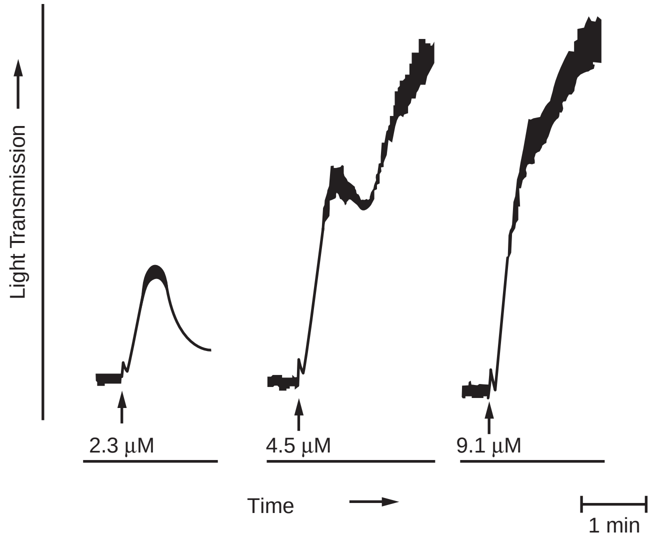

Figure 124.6 AGGREGATION RESPONSES OF PLATELETS IN CITRATED PLATELET-RICH PLASMA STIMULATED WITH ADP. (Note that the micromolar concentration of Ca^{2+} in citrated platelet-rich plasma is sufficient to allow aggregation to occur.) The *arrows* indicate the addition of increasing concentrations of ADP from left to right. Following addition of the agonist, platelet shape change is observed as a slight decrease in light transmission, followed by an increase in light transmission as the platelets aggregate. The lowest concentration of ADP (2.3 µM; *left*) induces primary aggregation followed by deaggregation, as indicated by the subsequent decrease in light transmission. The intermediate concentration of ADP (4.5 µM; *middle*) induces primary aggregation followed by a secondary wave of aggregation; the secondary wave occurs due to thromboxane A_2 formation by the activated platelets and subsequent granule content exocytosis, including ADP. At the highest concentration of ADP (9.1 µM; *right*), the two phases of aggregation merge so that only a single wave of aggregation is apparent. *(Adapted with permission from Rand ML, Leung R, Packham MA. Platelet function assays. Transfus Apher Sci. 2003;28:307.)*

with citrate, is routinely used in LTA assessment of platelet function (see Chapter 127). Citrate lowers the plasma concentration of Ca^{2+} to the micromolar range, which is still sufficient for aggregation to occur. In research laboratories, LTA of platelets isolated from plasma and suspended in balanced salt solutions (e.g., Tyrode's solution) is often used. In this case, Ca^{2+} must be added to the suspending medium to allow aggregation to occur. LTA measures platelet aggregation under conditions of low shear, in which aggregation is dependent on fibrinogen binding to activated αIIbβ3. This is in contrast with tests such as the Platelet Function Analyzer (PFA-100/200),[84,85] which measures aggregation under conditions of high shear (5000 to 6000 s^{-1}), in which aggregation is mediated by VWF binding to activated αIIbβ3.

Some of the commonly used platelet agonists are listed in Table 124.3. Of physiological relevance are the platelet-derived aggregating agents—ADP, and the arachidonic acid metabolite TxA_2—that provide a mechanism for stimulated platelets to recruit additional platelets to an aggregate in vivo. As described above, these agonists activate platelets by binding to specific receptors and triggering intracellular signaling pathways that ultimately converge to a set of common steps that permit the platelets to aggregate. Platelet aggregation, mediated by ligand binding to activated αIIbβ3, is energy and signal transduction dependent, and can be distinguished on this basis from platelet agglutination induced by ristocetin (see Table 124.3), mediated by VWF binding to GPIbα of the GPIb–IX–V complex, which does not require platelets to be metabolically active. Many preanalytical and analytical variables affect the results obtained by LTA and recommendations for clinical laboratory standardization have been published.[86–88]

Platelet aggregation can also be measured using whole-blood aggregometry. This test measures platelet aggregation in diluted, anticoagulated whole blood as the change in impedance or resistance between two electrodes when platelets adhere to the electrodes and aggregate in response to soluble agonists (see above and Table 124.3). Whole blood aggregometry has the advantages over LTA of requiring smaller blood volumes and less sample manipulation. Lumi-aggregometers provide simultaneous measurement of aggregation and dense granule secretion, specifically ATP release, via a luciferin-luciferase assay.

The information gained from aggregometry has been extremely useful in the diagnosis of platelet function disorders, whether inherited or acquired.[85,87,89] However, aggregation as measured in vitro does not always reflect platelet function in vivo; clinical bleeding and the aggregation response of platelets do not necessarily concur. This disparity reflects, in part, the importance of platelet adhesion under flow conditions in hemostatic plug/arterial thrombus formation, an effect that is not detected by aggregometry.[81] Tests that allow for measurement of platelet adhesion, activation, and aggregation on a variety of physiologically-relevant surfaces under flow conditions at variable shear rates, both physiological and pathological, and for measurement of multiple outcomes to characterize platelet responses will, in the future, provide additional information about platelet function.[90,91]

MOLECULAR BASIS OF INHERITED PLATELET DISORDERS

Inherited platelet disorders are a heterogeneous group of bleeding disorders involving defects in platelet function and/or number (usually thrombocytopenia). The bleeding symptoms experienced by patients are primarily mucocutaneous, such as epistaxis, bruising, bleeding from the oropharynx or gastrointestinal tract, heavy menstrual bleeding, and postpartum and surgical (including dental) bleeding (see Chapter 126). These symptoms can range from very mild to life threatening, depending on the disorder (severity may vary among individuals with the same disorder). While severe disorders such as GT and BSS are relatively easy to diagnose, milder disorders (e.g., those affecting secretion of granule contents) are more difficult to characterize and it is likely that they have a higher prevalence than previously appreciated[92]; the expected prevalence of clinically-significant predicted loss-of-function variants in platelet-associated genes is 0.3% in the general population.[93] Much has been learned about platelet development, structure and function, and the underlying genetic basis of specific disorders from the investigation of patients; indeed, the molecular defects in many of the disorders have now been identified (Fig. 124.7). Important insights have also been provided by characterization of mouse models in which platelet proteins have been altered genetically.[94–96] The reader is referred to comprehensive reviews of inherited disorders of platelets for more details.[97–100]

Inherited Platelet Function Disorders

Inherited platelet function disorders encompass defects in platelet adhesion, with deficiencies or dysfunction of receptors for subendothelial VWF or collagen; platelet activation, including deficiencies or dysfunction of receptors for soluble agonists, of cytoskeletal proteins, of signaling pathways, of dense and α-granule secretion, and of PS exposure; and platelet aggregation, with deficiencies or dysfunction of integrin αIIbβ3. Most of the disorders described below have an autosomal recessive pattern of inheritance, and thus affected individuals have homozygous or compound heterozygous gene variants. The disorders vary significantly in their severity, and some present with associated thrombocytopenia.

Abnormalities of Platelet Adhesion

GPIb–IX–V[15]

In BSS, variants in *GP1BA, GP1BB*, or *GP9* result in defective platelet surface expression of GPIb–IX–V, and thus a decreased ability of platelets to adhere to subendothelial VWF, as well as a decreased in vitro response of platelets to thrombin and ristocetin. Frameshift and nonsense (type 1 variants), and missense (type 2 variants) alterations have been described[14,101]; correlation of genotype with the moderate to severe bleeding phenotype in BSS is not apparent. The macrothrombocytopenia that occurs in BSS is discussed in the section Inherited Thrombocytopenias.

The autosomal dominant platelet-type VWD[102] is the result of gain-of-function variants in the VWF binding site on GPIbα. Enhanced binding of plasma VWF to GPIbα leads to platelet agglutination and a bleeding phenotype; (macro)thrombocytopenia may be present. In vitro, enhanced agglutination to low-dose ristocetin is observed. Platelet-type VWD is clinically indistinguishable, but genetically distinguishable, from type 2B VWD, caused by gain-of-function variants in the GPIbα binding site of VWF.

Collagen Receptors[103]

There is variability in the platelet surface expression levels of GPVI and α2β1 that are determined by specific haplotypes in *GP6* and *ITGA2*, respectively. Very rare deficiencies of α2β1 have been reported, associated with a mild bleeding diathesis and decreased in vitro platelet responses to collagen.[20] Several patients, including some from unrelated Chilean families, with *GP6* variants leading to deficiencies in GPVI expression have been described; they also have a mild bleeding phenotype with decreased in vitro responses of platelets to collagen. Acquired GPVI deficiency can also occur, with ectodomain shedding (i.e., cleavage) of the receptor from the platelet surface in response to autoantibodies.

Abnormalities of Platelet Activation

Soluble Agonist Receptors

Rare patients have been described with defects in the gene for the ADP receptor P2Y12 (*P2RY12*) or in the gene for the TxA_2 TP α receptor (*TBXA2R*). The defects mimic the effects of antiplatelet drugs: for *P2RY12*, clopidogrel, prasugrel, ticagrelor, and cangrelor, that block P2Y12; and for *TBXA2R*, aspirin, which blocks TxA_2 formation. As such, decreased platelet responses in vitro to ADP, and to arachidonic acid and the stable thromboxane mimetic U46619, respectively, are observed in these patients, who have a mild bleeding diathesis. There has been a recent first description of a rare variant in *F2RL3*, the gene for the PAR4 thrombin receptor, which is associated with decreased in vitro platelet responses to thrombin and the PAR4-activating peptide.[104]

Cytoskeletal Defects

These are discussed below in the section on Inherited Thrombocytopenias.

Secretion Defects

There are two types of disorders associated with deficiencies in granule secretion: (1) those due to defective platelet granule formation, low numbers of granules or absent cargo; and (2) those due to defects in secretion machinery, where granules are present, but contents are not secreted following platelet activation.

Dense Granules[105]

HPS is characterized by oculocutaneous albinism and platelet-dense granule deficiency.[106] The distinct HPS-1 to HPS-10 subtypes arise from defects in 10 genes, respectively: *HPS1*, *AP3B1*, *HPS3–6*, *DTNBP1*, *BLOC1S3*, *BLOC1S6*, and *AP3D1*. The protein products of these genes interact in BLOCs or in adaptor protein complex-3 (AP-3) that are involved in dense granule biogenesis.[54] Some subtypes are also associated with pulmonary fibrosis and granulomatous colitis. Patients with Chediak-Higashi syndrome have severe immunological defects in addition to oculocutaneous albinism and dense granule deficiency; they have variants in the *LYST* gene, the product of which is a vesicular transport protein. Non-syndromic dense granule deficiencies are relatively common. They are heterogeneous and include qualitative dense granule defects and their underlying molecular bases are unknown. Syndromic and non-syndromic dense granule deficiencies are associated with mild-to-moderate bleeding; in vitro secretion responses as measured by lumi-aggregometry are reduced or absent.[107]

Normal numbers of granules with decreased secretion responses are indicative of defective granule secretion processes. For example, in vitro evidence of dense and α-granule secretion defects with normal granule cargo are observed in some forms of familial hemophagocytic lymphohistiocytosis (FHL). Variants for genes encoding SNARE proteins or their regulators have been identified: Munc13-4 (*UNC13D*) in FHL3,[108] syntaxin-11 (*STX11*) in FHL4,[109] and Munc18b/syntaxin binding protein 2 (*STXBP2*) in FHL5.[110]

α-Granules

The classic α-granule deficiency, gray platelet syndrome (GPS), is discussed in the section on Inherited Thrombocytopenias. Platelet α-granules are also absent in the multisystem disorder ARC (arthrogryposis-renal dysfunction-cholestasis) syndrome, which is lethal within the first year of life. Here, the gene defect is in *VPS33B*, which encodes a Sec1/Munc18 interacting protein involved in intracellular vesicular trafficking, or in *VIPAS39* (*VPS16B*), which encodes VPS33B-interacting protein. While α-granules are present in platelets from patients with the autosomal dominant Quebec platelet disorder (QPD), their contents are proteolytically degraded by plasmin generated by urokinase-type plasminogen activator (u-PA), with overexpression related to tandem duplication of *PLAU*, the u-PA gene.[111] Increased fibrinolysis after platelet secretion results in delayed bleeding after surgery or trauma; in vitro platelet responses to epinephrine are decreased.[107]

Signaling Pathways

Patients have been identified with apparent congenital disorders in a variety of signaling pathways involving G proteins (G_q, G_s, G_i), $cPLA_2$, and PLC, PKC-θ, Ca^{2+} mobilization, TxA_2 formation (including COX-1 and thromboxane synthase deficiencies), and granule secretion.[112] However, for the most part, the underlying genetic defects in these patients, who experience mild-to-moderate bleeding, remain unknown. The following are several disorders for which the underlying genetic defects are known. An insertion variant in the extra-large $G\alpha_s$ gene (*GNASXL*) has been associated with $G\alpha_s$ hyperfunction in platelets and a bleeding phenotype, neurological problems, and mild skeletal abnormalities. A gain-of-function variant in *SRC*, that encodes the tyrosine kinase Src, results in an autosomal dominant disorder characterized by thrombocytopenia, bleeding, abnormal platelet α-granules, myelofibrosis and bone pathologies.[113,114] A gain-of-function variant in *STIM1* resulting in a CRAC channelopathy has been shown in the autosomal dominant Stormorken syndrome, which is characterized by a mild bleeding diathesis, thrombocytopenia, and, in resting platelets, elevated $[Ca^{2+}]_i$ and surface PS exposure. The York platelet syndrome, characterized by thrombocytopenia, ultrastructural abnormalities in platelet organelles, and deficiency of Ca^{2+} storage in dense granules, has also been identified as a CRAC channelopathy due to the same gain-of-function variant in *STIM1* that is found in Stormorken syndrome. Variants in *PLA2G4A* encoding cPLA2, in *PTGS1* encoding COX, and in *TBXAS1* encoding thromboxane synthase (Ghosal syndrome) have been described.

PS Exposure

Scott syndrome, in which there is a defect in PS exposure and thus, platelet procoagulant activity, is associated with variants in *TMEM16F* (*ANO6*)[75]; TMEM16F (anoctamin 6) is essential for Ca^{2+}-dependent PS exposure. There is diminished platelet-derived extracellular vesicle formation. Decreased thrombin generation results in a moderate-to-severe bleeding phenotype; in vitro platelet aggregation responses are not affected and therefore not helpful in making the diagnosis.

Abnormalities of Platelet Aggregation

$\alpha IIb\beta 3$[115,116]

One of the best characterized platelet function disorders, GT, results from quantitative or qualitative defects of the fibrinogen/VWF receptor αIIbβ3, and thus the inability of platelets to aggregate. The bleeding phenotype ranges from mild to life-threatening hemorrhage, and in vitro there are absent aggregation responses to all agonists, while ristocetin-induced agglutination is intact. Type I GT is defined as less than 5% surface-expressed αIIbβ3; type II, as 5% to 25%; and variant, as normal expression levels of an αIIbβ3 complex that is nonfunctional. Approximately 200 variants have been described in the *ITGA2B* and *ITGB3* genes, most commonly missense and nonsense variants, and those involving splice variants and small deletions and insertions with frame shifts; genotype does not correlate with phenotype.[117] Rare variants result in macrothrombocytopenia (see section on Inherited Thrombocytopenias).

Defects in the gene for CalDAG-GEFI (*RASGRP2*)[118,119] or kindlin-3 *(FERMT3)* have been reported that prevent activation of αIIbβ3, with subsequent absence of platelet aggregation. Deficiency in kindlin-3 is the basis for leukocyte deficiency-adhesion III syndrome, a severe disorder that encompasses defective integrin β2 function in leukocytes and associated susceptibility to infections and poor wound healing, as well as severe bleeding.

Inherited Thrombocytopenias

Inherited thrombocytopenias vary in severity, platelet morphology, and presence or absence of associated platelet dysfunction. Some types are associated with congenital anomalies and some with predisposition to additional diseases, including malignancy. The advent of high throughput sequencing has greatly enhanced our understanding of known disorders, and the identification of previously unexplained disorders, by identifying causal gene variants; presently defects in upwards of 40 human genes are known to be associated with inherited thrombocytopenias.

The pathogenesis of inherited thrombocytopenias can best be understood in the context of platelet biogenesis and senescence, with defects occurring in megakaryocyte differentiation, maturation, proplatelet formation and platelet release, and in alterations in platelet survival (see Fig. 124.7; see also Chapter 123).[120,121]

Abnormalities of Megakaryocyte Differentiation

Defects in the maturation of hematopoietic stem cells into megakaryocytes result in deficiency or absence of bone marrow megakaryocytes. Examples of differentiation defects:

Congenital Amegakaryocytic Thrombocytopenia

Congenital amegakaryocytic thrombocytopenia (CAMT) is an autosomal recessive disease caused by variants in *MPL*, the gene encoding the thrombopoietin (TPO) receptor (Mpl). Binding of TPO to its receptor activates multiple signaling pathways including JAK2/STAT, Ras/MAPK, and PI3K.[122] Disease severity depends on the specific variant that results in either complete absence of Mpl or some residual Mpl. TPO signaling is essential for commitment and differentiation in megakaryocytes but also in the erythroid and myeloid lineages. Patients with CAMT, who have isolated thrombocytopenia at birth, usually develop trilineage bone marrow hypoplasia in childhood.[123]

Thrombocytopenia With Absent Radii

Thrombocytopenia with absent radii (TAR) is an autosomal recessive disorder characterized by absent radii and isolated thrombocytopenia, also present at birth. In contrast to CAMT, platelet counts improve with age and other cell lines are unaffected. The cause is compound inheritance of a low-frequency single-nucleotide variant and a rare null allele in *RBM8A*, a gene encoding the exon-junction complex subunit member Y14. This complex is involved in RNA processing and nuclear export. It is still unknown how this defect results in the TAR phenotype or megakaryocyte differentiation, although it may affect the response of hematopoietic progenitors to TPO.[124,125]

Amegakaryocytic Thrombocytopenia With Radio-Ulnar Synostosis

Amegakaryocytic thrombocytopenia with radio-ulnar synostosis (ATRUS) is the result of heterozygous defects in *HOXA11*, a member of the *HOX* gene family of transcription factors involved in embryonic development. These patients have thrombocytopenia from birth that does not improve with time, associated with fusion of the proximal radius and ulna.[123]

Abnormalities of Megakaryocyte Maturation

Altered maturation is characterized by immature, dysplastic or dysfunctional megakaryocytes. Many of these conditions are the result of defects in transcription factors involved in megakaryopoiesis (e.g., *RUNX1, FLI1, GATA1, ETV6*), and some are associated with platelet function defects and/or an increased risk of malignancy. Examples of maturation defects:

Familial Platelet Disorder With Predisposition to Myeloid Malignancy

Familial platelet disorder with predisposition to myeloid malignancy (FPDMM) is the result of heterozygous variants in *RUNX1* (also called *AML1* or *CBFA2*) that encodes the alpha subunit of the core-binding factor transcription complex. This complex regulates expression of genes involved in stem cell proliferation versus differentiation in hematopoiesis. The loss of this regulation results in failure of megakaryocyte maturation. *RUNX1* also regulates synthesis of specific proteins that can alter platelet function and result in abnormalities of platelet granule structure or granule secretion.[126] Germline *RUNX1* variants predispose to the development of myelodysplastic syndrome and acute *myeloid* leukemia in approximately 40% of individuals.[127]

Paris-Trousseau Thrombocytopenia and Jacobsen Syndrome

Paris-Trousseau thrombocytopenia and Jacobsen syndrome are disorders caused by deletions in chromosome 11q23-ter; the severity of the syndrome, which includes cardiac and facial defects, depends on the size of the deletion. Heterozygous loss of the transcription factor gene *FLI1* results in macrothrombocytopenia, abnormal α-granules and internal membrane structure (see Chapter 123).[126]

ANKRD26-Related Thrombocytopenia

ANKRD26-related thrombocytopenia (*ANKRD26*-RT) is an autosomal dominant inherited thrombocytopenia, the result of point variants in the 5′-UTR of *ANKRD26*. *ANKRD26* expression is normally downregulated during megakaryocyte maturation by the binding of RUNX1/FLI1 to the 5′-UTR. Lack of binding by these co-regulators because of the alterations in the 5′-UTR, leads to a persistent expression of ANKRD26, increased downstream signaling, and dysmegakaryopoiesis.[128] Affected individuals are at increased risk of developing myelodysplastic syndrome and some also have evidence of dysregulation of erythroid cell maturation.[129]

ETV6-Related Thrombocytopenia

Germline heterozygous variants in *ETV6* lead to autosomal dominant thrombocytopenia and a predisposition to lymphoid malignancy.[130] A transcriptional regulator, ETV6 normally dimerizes with FLI1, suggesting that abnormal interactions between ETV6 and FLI1 may contribute to defects in downstream expression of platelet proteins involved in regulation of cytoskeletal dynamics and platelet maturation.

GATA-1-Related Thrombocytopenias

These are X-linked diseases associated with anemia, indicating this transcription factor's involvement in both megakaryocytic and erythroid maturation (see Chapter 123). Variants in GATA-1 that interfere with binding to its cofactor FOG1 result in dyserythropoietic anemia with thrombocytopenia and defects in α-granule maturation.[97]

Gray Platelet Syndrome

Gray platelet syndrome (GPS) is the result of homozygous variants in *NBEAL2*, a regulator of membrane dynamics and vesicle trafficking, affecting α-granule development. The disorder is characterized by progressive macrothrombocytopenia, absent platelet α-granules, splenomegaly, immune dysregulation and myelofibrosis.[56–58,131] Platelets appear pale gray on stained blood films because of the absence of α-granules. The *Nbeal2*$^{-/-}$ mouse also shows evidence of abnormal megakaryocyte maturation,[132] defects in retention of α-granule cargo proteins,[133] and poor wound healing.

Heterozygous variants in *GFI1B*, encoding a transcription factor involved in megakaryopoiesis and erythropoiesis, have been identified in association with a phenotype similar to GPS. Affected individuals have macrothrombocytopenia and α-granule deficiency, and some have erythrocyte abnormalities.[134]

Abnormalities of Proplatelet Formation and Platelet Release

Defects in proplatelet formation and the conversion of proplatelets to platelets are the basis for this group of thrombocytopenias, the majority of which are macrothrombocytopenias.

Variants in genes encoding platelet cytoskeletal components (e.g., *MYH9, ACTN1, FLNA*), the microtubule system (e.g., *TUBB1*), or surface membrane receptors that interact with the cytoskeleton (e.g., *GP1BA*, *ITGA2B*, *ITGB3*) can lead to these diseases. Examples of defects in proplatelet formation and platelet release include:

MYH9-Related Disease[135]

Previously referred to as the May-Hegglin, Sebastian, and Fechtner syndromes and Epstein anomaly, *MYH9*-related disease is the result of autosomal dominant variants in *MYH9*, the gene that encodes NMMHC-IIA. NMM is involved in the generation of energy-driven skeletal forces involved in cytokinesis, cell motility, and shape change. MYH9 is composed of two main domains, N-terminal and tail domains. The N-terminus of the myosin heavy chain is composed of the head or motor domain that interacts with actin and binds ATP, and the neck domain that binds myosin light chains. The C-terminal tail domain is involved in dimerization of the heavy chains and in phosphorylation. Affected individuals have macrothrombocytopenia from birth, the result of decreased proplatelet formation related to abnormal distribution of actin-myosin cytoskeleton and abnormal migration on collagen that may lead to ectopic and ineffective proplatelet formation.

Neutrophils contain cytoplasmic clusters of MYH9 protein that can be identified by immunofluorescence microscopy. In some patients, these inclusions can be seen on May-Grünwald-Giemsa-stained blood films (Döhle-like bodies). Approximately 35% of affected individuals develop nephropathy that evolves to end-stage renal disease, 20% develop early-onset cataracts, and 50% develop sensorineural hearing loss.[51] There is a correlation between the clinical phenotype and the specific variant: motor domain variants are often associated with hearing loss and nephritis in addition to thrombocytopenia, while those in the tail domain are associated with moderate thrombocytopenia, only.

ACTN1- and FLNA-Related Thrombocytopenias

These result from variants in the genes that encode α-actinin or filamin A, both functioning as cross-linking proteins in the actin-based cytoskeleton. Filamin A is also critical in binding the cytoplasmic tail of GPIbα to the filamentous actin network and stabilizing αIIbβ3 in its resting state. Monoallelic variants of either gene result in abnormalities of proplatelet formation and variable degrees of macrothrombocytopenia.[45,121]

Bernard-Soulier Syndrome

In addition to the functional adhesion defect (described in the section on Abnormalities of Platelet Adhesion), patients with BSS have thrombocytopenia with giant platelets. Abnormalities in proplatelet formation resemble those seen in variants of cytoskeletal proteins, suggesting that the anchoring of the actin filament network by GPIbα to the plasma membrane is a required part of this process, disrupted by deficiency of the GPIb–IX–V transmembrane protein complex.[12,121] Most heterozygotes do not have macrothrombocytopenia, but there are exceptions where specific monoallelic variants in *GPIBA* (e.g., p.A156V, the Bolzano variant) or *GPIBB*[136] cause mild macrothrombocytopenia. Mild to moderate thrombocytopenia is also observed in 22q11.2 deletion syndrome (velocardiofacial/DiGeorge syndrome) in which there is a hemizygous (usually) somatic deletion at chromosome 22q11.2 that includes *GPIBB*; this syndrome can be associated with additional developmental defects.

ITGA2B/ITGB3-Related Thrombocytopenias

These are rare macrothrombocytopenias with functional defects associated with specific monoallelic variants in *ITGA2B* or *ITGB3* that are distinct from the variants that cause GT, described previously. These variants result in constitutive activation of αIIbβ3 and downstream effectors, defects in actin-myosin reorganization, and abnormalities of proplatelet formation.[137]

TUBB1-Related Thrombocytopenia

This is caused by variants in the gene encoding β1-tubulin that impact its association with α-tubulin and result in abnormalities in assembly of the microtubule coil.[138] This defect in the microtubule coil leads to production of fewer proplatelets with abnormal morphology. Platelets are spherical rather than discoid (see also Chapter 123). Platelet counts and bleeding manifestations are highly variable.

PRKACG-Related Macrothrombocytopenia

This is the result of a germ-line variant in the gene encoding the γ -catalytic subunit of the cAMP-dependent protein kinase (PK), PKA. There is a defect in proplatelet formation and a low level of filamin A in megakaryocytes.[139]

Wiskott-Aldrich Syndrome and Other Microthrombocytopenias

Wiskott-Aldrich syndrome (WAS) and X-linked thrombocytopenia (XLT), both microthrombocytopenias are caused by variants in the *WAS* gene. Pathogenic variants that result in non-expression of WASp cause WAS, which manifests as severe immune dysregulation, in addition to thrombocytopenia. XLT is caused by hypomorphic variants that decrease but do not abolish expression of the normal WASp. WASp is involved in regulation of actin polymerization; the defect in platelet production may be the result of ectopic platelet shedding by megakaryocytes.[120,140]

Recently, other causes of microthrombocytopenia have been identified including deficiency in ARPC1B (ARP 2/3 complex 1B), which is activated by the WASp complex and plays an important role in actin nucleation and polymerization. Germline variants in *ARPC1B* are associated with defects in platelet and T-cell function, leading to a severe immunodeficiency.[141,142]

PLATELETS BEYOND HEMOSTASIS

Although platelets were originally identified for roles in hemostasis and arterial thrombosis, they have become well-recognized for their involvement in a myriad of other physiological and pathological processes, including wound healing/tissue repair; infection, (innate and adaptive) immunity, and inflammation; (development and progression of) malignancy and tumor metastasis; (lymph)angiogenesis; and neurodegenerative diseases. Some of these have been briefly touched on in sections above (see The Integrin Family of Adhesion Receptors; CLEC-2; Secretion of Granules; and Platelet-Derived Extracellular Vesicles).

Many of the same mechanisms that play a role in hemostasis and thrombosis facilitate platelet participation in these non-hemostatic processes. Platelet receptors such as αIIbβ3, GPIb-IX-V, GPVI, CLEC-2, P-selectin, CD40/CD40L, FcγRIIA, and TLRs (Toll-like receptors) have been implicated in tumor progression and metastatic spread; in the immune response to bacterial challenge; in the progression of inflammatory conditions such as atherosclerosis and rheumatoid arthritis. The intense inflammation accompanying infection with the SARS-CoV-2 virus (COVID-19) is associated with platelet-platelet and platelet-leukocyte interactions that contribute to the significant incidence of thrombosis in this disease.[143,144] SARS-CoV-2 virions have been detected in megakaryocytes and platelets of COVID-19 patients, and platelets from these patients are hyper-reactive and have a distinct prothrombotic transcriptome profile.[144,145] Platelets are not directly activated by SARS-CoV-2 as they lack the ACE2 receptor for the virus; the mechanism may be anti SARS-CoV-2 immune complexes that bind and activate the FcγRIIA receptor leading to granule secretion and procoagulant surface exposure.[144,146]

The secretion of platelet granule contents, including adhesive proteins, growth factors and chemokines/cytokines, that serve to facilitate wound healing/tissue repair, also function in acute and chronic inflammatory disease; in angiogenesis, including tumor angiogenesis; in tumor cell activation and growth; and in the progression of Alzheimer disease. Platelet-derived extracellular vesicles contribute to inflammatory conditions such as rheumatoid arthritis and to the platelet-cancer nexus. Platelets contribute to host defense as they recognize bacteria, recruit traditional immune cells to sites of infection and secrete bactericidal mediators. They can bind, internalize and clear a variety of viruses. The reader is referred to comprehensive reviews of non-hemostatic roles of platelets for details.[24,147–154]

PLATELET AGGREGATION TESTING FOR THE DIAGNOSIS OF PLATELET DISORDERS

Platelet aggregometry is the mainstay in the work-up of platelet function disorders (PFDs). Abnormalities in aggregation tracings can point towards specific diagnoses and direct further testing.

Glanzmann Thrombasthenia

In this severe PFD in which there are quantitative or qualitative defects in integrin αIIbβ3 (GPIIb–IIIa), the receptor to which fibrinogen/von Willebrand factor (VWF) binds on activated platelets, there is absent aggregation response to all agonists. However, agglutination in response to ristocetin occurs, as it is independent of αIIbβ3.

Bernard-Soulier Syndrome

This disorder with defective surface expression of the adhesive VWF receptor GPIb–IX–V is characterized by a lack of agglutination to ristocetin. Note that in von Willebrand disease (VWD), there is an absent agglutination response to ristocetin because of deficient VWF.

Defects in Agonist/Adhesion Receptors

P2Y12: a defect in this ADP receptor results in decreased and reversible aggregation responses to ADP. TPα: thromboxane A_2 (TxA_2) receptor defects show decreased aggregation responses to arachidonic acid, collagen and the stable TxA_2 mimetic U46619. GPVI: a defect in this collagen receptor is characterized by a decreased aggregation response to collagen.

Storage Granule Deficiencies/Secretion Defects

In these disorders, secondary aggregation responses to ADP, collagen, epinephrine, and arachidonic acid can be reduced, but it should be noted that secretion defects may be present with a normal aggregation profile. In dense granule disorders, secretion as measured by lumi-aggregometry is decreased.

Platelet Type VWD/Type 2B VWD

These gain-of-function disorders in the VWF-binding site of GPIbα and in the GPIbα-binding site of VWF, respectively, are characterized by an abnormally increased agglutination response to a low concentration of ristocetin.

Effects of Antiplatelet Medications

Aggregation responses are also affected by antiplatelet medications. For example, individuals taking aspirin or other nonsteroidal anti-inflammatory drugs have decreased platelet aggregation responses to arachidonic acid, but not to U46619. Patients taking P2Y12 receptor blockers (i.e., clopidogrel, prasugrel, ticagrelor, or cangrelor) will have decreased and/or reversible aggregation responses to ADP, depending on the extent of inhibition of the receptor.

CHAPTER 125

MOLECULAR BASIS OF BLOOD COAGULATION

Kathleen Brummel-Ziedins, Kenneth G. Mann, James C. Fredenburgh, and Jeffrey I. Weitz

Blood is the principal vehicle delivering oxygen and nutrients to the various tissues and organs of the body. Blood flow and the integrity of the vasculature are essential to life itself. The hemostatic process has evolved to provide damage recognition and protection from blood loss after perforation of the vasculature while at the same time preventing the systemic activation of the clotting system. However, pathologic occlusions are associated with dysregulation of the intravascular system, resulting in venous or arterial thrombosis. The fine line between vascular occlusion and hemostasis is defined by the complex interplay between pro- and anticoagulant materials provided by the blood, the vasculature, and subvascular elements. The appropriate functions occur as a consequence of intense focal development and regulation of enzymatic activity at sites of vascular injury.

The development of the inventory of components involved in plasma clotting were initially based on the most abundant procoagulant plasma proteins, notably prothrombin and fibrinogen, and extended during the past century with the identification of genetic abnormalities that led to bleeding and deviations in laboratory tests that evolved as the inventory of congenital defects expanded. In some instances, laboratory test results indicating a defect in the procoagulant system were not mirrored by hemostatic pathology. In a similar fashion, the congenital defects associated with thrombosis led to the discovery of anticoagulant proteins in blood and vascular counterparts associated with their presentation and activation.

The functional connections between procoagulant "factors" were developed by mixing and matching plasmas associated with different hemostatic disorders. This inventory and its connectivity were ratified and expanded by experiments performed with transgenically mutated mice.

The dynamics of the plasma coagulation process as expressed are a consequence of the molar concentrations of the pro- and anticoagulant components in blood and the vasculature, and the kinetic processes associated with the dynamics of both the activation and functions of the various proteins associated with the process.

The initial result of the activation of the procoagulant hemostatic process is the formation of a fibrin–platelet plug that forms the temporary seal of the vascular perforation in hemostasis. The generation of an occlusive fibrin–platelet plug blocking further flow through an element of the vasculature is thrombosis. In both instances, the fibrin–platelet scaffold is ultimately removed and substituted by vascular repair, new cells, and connective tissue. In thrombosis, the platelet–fibrin plug is removed mechanically or by biochemical intervention to restore flow to the flow-starved vascular bed.

The elements of a clotted fibrinogen–platelet plug are dissolved by the fibrinolytic system, a tightly regulated, dynamic system involving enzyme activation, feedback regulation, and blockade by a potent series of inhibitors. Just as there is an interplay between the pro- and anticoagulant components that brings about a blood clot in hemostasis, similar mechanisms occur when blood clots are dissolved via the fibrinolytic process, which is essential for tissue repair. This chapter describes the components of the pro- and anticoagulant system and the pro- and antifibrinolytic system, and the interplay between these systems. The common feature of both systems is the focal presentation of activity that is dependent on the presentation of surface-bound enzymatic complexes that can cleave their respective substrates.

Blood coagulation can best be understood if viewed as a choreographed system that starts from an inventory of the key players, the relationship or connectivity of these players, and the dynamic catalytic processes. These processes together keep blood in a fluid state but primed to react to vascular injury in an explosive manner. Therefore following sections describe the process of blood coagulation in terms of the inventory, the connectivity, and then the dynamics.

INVENTORY: PROCOAGULANT, ANTICOAGULANT, AND FIBRINOLYTIC PROTEINS, INHIBITORS AND RECEPTORS

Putting together an inventory of the blood coagulation components is still ongoing, but what we currently know to date began from initial observations that were made in the fifth century and recorded in the Babylonian Talmud. It was noted that if two male children died of bleeding after circumcision, the third should not be circumcised.[1] Over the centuries, many more hypotheses were made regarding what happens to blood when it escapes from the body.[2,3] The realization that clots stem blood loss only occurred in the 18th century.[2,3] The existence of thrombin, the key enzyme in blood coagulation, was recognized in the 19th century.[2,4]

In 1905, Paul Morawitz proposed the classic theory of coagulation.[5] He hypothesized that in the presence of calcium and thromboplastin, prothrombin was converted to thrombin, which in turn converted fibrinogen to the fibrin clot. These clotting factors were subsequently assigned Roman numerals, factor I (fibrinogen), factor II (prothrombin), factor III (thromboplastin; tissue factor membrane), and factor IV (calcium).[6] As more coagulation factors were introduced, they were assigned consecutive Roman numerals. The activated forms are distinguished by a lower case "a" after their Roman numeral designation. Therefore, the activated form of factor V becomes factor Va.

More complex descriptions of the coagulation system were as a "cascade" or "waterfall." Macfarlane[7] and Davie and Ratnoff[8] proposed that in an intrinsic pathway, involving only plasma, blood coagulated by a sequence of events in which the reactions occurred in a defined series leading to fibrin clot formation. Over the past six decades, the Morawitz/Davie and Macfarlane pathways have been significantly expanded (Fig. 125.1). Each reaction shares a similar mechanism in which an inactive zymogen protein is converted to an active enzyme and each "enzyme" is a surface-bound multiprotein complex consisting of a surface, divalent calcium ions (Ca^{2+}), a protease, and a cofactor. Although some facets of these initial descriptions are still valid, the emerging concept of coagulation and fibrinolysis centers on a complex network of highly interwoven concurrent processes. Procoagulant and fibrinolytic events occur simultaneously with many positive- and negative-feedback loops regulating the processes.

To fully understand the multiple simultaneous processes that occur to effect a hemostatic response, we will first inventory the key procoagulant, anticoagulant, and fibrinolytic participants. The inventory sections discuss the vitamin K–dependent protein family,

Figure 125.1 OVERVIEW OF HEMOSTASIS. Coagulation is initiated via two pathways, the primary extrinsic pathway *(right)* and the accessory (historically called the contact or intrinsic) pathway *(left)*. An illustration of the multistep processes is as follows: enzymes *(small circles)*, inhibitors *(large circles)*, zymogens *(boxes)*, or complexes *(ovals)*. The accessory pathway has no known bleeding etiology associated with it; thus, this pathway is considered an accessory to hemostasis. Upon injury to the vessel wall, tissue factor, the cofactor for the extrinsic tenase complex, is exposed to circulating factor (F) VIIa and forms the vitamin K–dependent complex extrinsic tenase. FIX and FX are converted to the serine proteases factor IXa (FIXa) and factor Xa (FXa), which then form the intrinsic tenase and prothrombinase complexes, respectively. The combined actions of intrinsic and extrinsic tenase complexes and the prothrombinase complex lead to an explosive burst of thrombin (FIIa). Thrombin not only functions as a procoagulant but also acts as an anticoagulant when complexed with the cofactor thrombomodulin in the protein Case complex. The product of the protein Case reaction, activated protein C (APC), inactivates the cofactors FVa and FVIIIa. The cleaved species, factor Vai (FVai) and factor VIIIai (FVIIIai), no longer support the respective procoagulant activities of the prothrombinase and intrinsic tenase complexes. When thrombin is generated through procoagulant mechanisms, thrombin cleaves fibrinogen, releasing fibrinopeptide A (FPA) and fibrinopeptide B (FPB), and activates FXIII to form a cross-linked fibrin clot. Thrombin–thrombomodulin also activates thrombin activatable fibrinolysis inhibitor (TAFI), which delays fibrin degradation by plasmin. The procoagulant response is downregulated by the stoichiometric inhibitors tissue factor pathway inhibitor (TFPI) and antithrombin (AT). TFPI attenuates the activity of extrinsic tenase, the trigger of coagulation. AT directly inhibits thrombin, FIXa, and FXa. The accessory pathway provides an alternate route for the generation of FIXa. Thrombin has also been shown to activate FXI. *HMWK*, High-molecular-weight kininogen.

The Vitamin K–Dependent Protein Family

Vitamin K–dependent proteins, synthesized in the liver, play a central role in blood coagulation through either procoagulant or anticoagulant mechanisms. The vitamin K–dependent protein family includes the zymogen procoagulant factors VII, IX, X, and prothrombin, and the anticoagulants protein C, protein S, and protein Z (Fig. 125.2 and Table 125.1). Except for protein S and protein Z, after cleavage to their active forms these proteins are serine proteases related to the trypsin and chymotrypsin superfamily. Peptide bond cleavage at specific sites converts the vitamin K–dependent zymogens to their active serine protease forms. All share noncatalytic domains, each of which is characterized by highly conserved regions that fold, independently from the rest of the molecule, into a characteristic three-dimensional shape. The domains of the vitamin K–dependent proteins are illustrated in Fig. 125.2. Several reviews have been written on vitamin K–dependent proteins.[9–11]

Vitamin K is essential for the biosynthesis of these clotting factors by participating in the cyclic oxidation and reduction of the enzyme that converts 9 to 13 N-terminal glutamate residues to γ-carboxy glutamate (Gla; Fig. 125.2; see reviews listed in the References[9,12–14]). This posttranslational modification to form Gla residues adds a net negative charge to the molecules that enables the vitamin K–dependent proteins to interact with Ca^{2+} and a membrane surface.[15,16] Blocking the formation of the Gla residues is the basis for anticoagulant therapy with coumarin (warfarin) derivatives, which are chemically similar in structure to vitamin K (Fig. 125.3). Figure 125.2 SCHEMATIC REPRESENTATION OF THE VITAMIN K–DEPENDENT PROTEINS. The vitamin K–dependent proteins can be divided into two classes, procoagulant (factors II, VII, IX, and X) and anticoagulant (protein C, protein S, and protein Z). The building blocks for these proteins include an NH_2-terminal Gla domain, consisting of 9 to 13 Gla residues, followed by either an EGF–like domain in factor VII, factor IX, factor X, protein C, protein S, and protein Z, or a K domain in prothrombin. In protein S, a TSR precedes the EGF domain. Active sites are contained within the serine protease domain. Cleavage sites for the conversion of zymogens to their active forms are designated by boxes above the arrows. Factor IX, factor X, and protein C are activated by proteolytic removal of an AP. Protein S, which is not a serine protease precursor, contains an SHGB at the COOH-terminus. Protein Z also contains a "pseudo catalytic domain" in the COOH-terminus and does not function as a serine protease. Disulfide bonds (-S-S-) critical to the integrity of the two-chain zymogens or active forms are presented. *AP*, Activation peptide; *EGF*, epidermal growth factor; *K*, kringle; *SHGB*, sex hormone–binding globulin–like domain; *TSR*, thrombin-sensitive region.

binding association with this modification is also the basis for the anticoagulant activity of sodium citrate, a calcium chelator, found in the blue-top vacuum tubes used for clinical laboratory testing of clotting activity. The level of inhibition achieved with the same dose of warfarin varies among patients. Increased sensitivity to warfarin has been identified in patients when started after surgery.[17,18] Factors affecting the level of anticoagulation include dietary intake of vitamin K; liver function; concomitant medications that either reduce or enhance the warfarin effect[19]; common polymorphisms in the vitamin K epoxide reductase complex subunit 1 (VKORC1), which is responsible for vitamin K reduction; and polymorphisms in CYP2C9, which affect warfarin metabolism (see reviews listed in the References[20,21]). Therefore, genotyping may be helpful to personalize starting doses of warfarin. Ultimately, proper monitoring of warfarin therapy is essential. This is done using the prothrombin time (PT) with the assay sensitivity corrected using the international normalized ratio (INR).[22,23]

The NH_2-terminal Gla domains are followed by either a kringle domain in factor II or an epidermal growth factor–like domain (EGF) in factor VII, factor IX, factor X, protein C, protein S, and protein Z (see Fig. 125.2). Protein S is not a serine protease precursor and instead contains a thrombin-sensitive region before the EGF domain and a sex hormone–binding globulin–like domain (SHBG) in the COOH-terminus.[24] Protein Z contains a "pseudo catalytic domain" in the COOH-terminus and does not function as a serine protease enzyme.[25]

Vitamin K–dependent protein complexes are essential for establishing hemostatic balance (Fig. 125.4). Each complex is composed of

Figure 125.3 VITAMIN K–DEPENDENT PROCESS AND WARFARIN EFFECT. Schematic representation of the mechanism of γ-carboxy glutamate generation by a vitamin K–dependent reaction cycle to produce an active protein is illustrated. The regeneration of vitamin K hydroquinone by the vitamin K–dependent reductases is inhibited by warfarin.

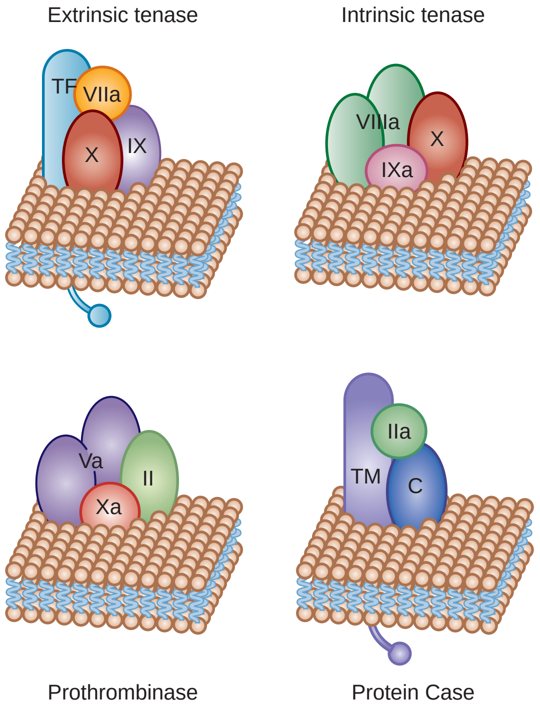

Figure 125.4 VITAMIN K–DEPENDENT COMPLEXES. Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each membrane complex consists of a vitamin K–dependent serine protease (factor VIIa [VIIa], factor IXa [IXa], factor Xa [Xa], or thrombin [IIa]) and a soluble or cell surface–associated cofactor (factor VIIIa [heavy and light chain $VIII_H$ and $VIII_L$], factor Va [heavy and light chain V_H and V_L], tissue factor [TF], or thrombomodulin [TM]). Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate(s) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants, enhancing the reaction rates by 10^4- to 10^9-fold.

When the serine protease is associated with its respective cofactor on an appropriate membrane surface with Ca^{2+}, the specific reactions occur at a rate that is 10^4- to 10^9-fold faster than that of protease–substrate combination alone.[26] One way to visualize the importance of the assembly of these macromolecular complexes in the formation of the hemostatic plug is to note that if a healthy person takes 4 minutes for his or her blood to clot, then in the absence of membrane and cofactor, blood clot formation would take approximately 3.8 years.

Cofactor Proteins

There are two categories of procoagulant cofactor proteins: the cell-bound cofactors (tissue factor and thrombomodulin) and the soluble plasma-derived procoagulant procofactors (factor V and factor VIII with its circulating carrier von Willebrand factor [vWF]).

Cell-Bound Cofactors

Tissue Factor

Tissue factor is a transmembrane protein that functions as a nonenzymatic cofactor for factor VIIa in the extrinsic tenase complex[27] (see reviews listed in the References[28,29]; Fig. 125.5A). In the absence of injury or inflammatory stimuli, tissue factor is not expressed on cellular surfaces in direct contact with circulating blood (see the review listed in the References[30]). Presentation of tissue factor to the circulation is the event that triggers the primary procoagulant pathway of coagulation (see Fig. 125.1).[31–33] There are no known mutations or deficiencies of human tissue factor, and tissue factor deletion in mice is lethal during embryonic development,[34] leading to the speculation that tissue factor is essential for life.

Tissue factor activity is primarily regulated by controlling its presentation. The commonly accepted sources of functional tissue factor are the subendothelium exposed upon vascular damage or monocytes stimulated by cytokines. However, there is controversy regarding the source and presentation of active tissue factor and whether functional

Figure 125.5 CELL-BOUND AND SOLUBLE COFACTOR STRUCTURES . (A) Cell-bound cofactors: tissue factor and thrombomodulin. Tissue factor is composed of an extracellular domain (residues 1–219), a transmembrane domain (residues 220–242), and a cytoplasmic domain (residues 243–263). Two disulfide bonds (-S-S-) are identified. One cysteine (C^{245}) contains a thiol ester linkage to a fatty acid. Tissue factor, which is the cofactor for factor VIIa in the extrinsic tenase complex, is exposed on the subendothelial surface after injury. Thrombomodulin is an endothelial cell-surface glycoprotein composed of five distinct domains. These include a lectin-like domain (residues 6–149), a domain containing six EGF–like regions (residues 227–462), a small extracellular domain rich in threonine and serine residues (S^{472} and S^{474} have been identified as sites of chondroitin sulfate adducts), a membrane-spanning region (residues 499–521), and a cytoplasmic tail (residues 522–557). There are nine known glycosylation sites on the thrombomodulin molecule. Thrombomodulin functions as the cofactor in the protein Case complex and assists in the generation of activated protein C. (B) Soluble plasma procofactors: factor VIII and factor V. The linear domain structures (A1–A2–A3–C1–C2) are illustrated. The B regions (factor V, residues 709–1545; factor VIII, residues 740–1689) connecting the A2 and A3 domains are shown by *dotted* (factor VIII) or *jagged* (factor V) lines. *EGF*, Epidermal growth factor.

tissue factor circulates in blood in healthy and pathologic states.[35–40] Microparticle sources of blood-borne tissue factor are generally defined as submicron-sized cell-derived membrane fragments produced in response to activation or apoptosis. Their role in hemostasis is still debated.[28,35,41,42]

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein constitutively expressed on the surface of vascular endothelial cells (see Fig. 125.5A). Thrombomodulin is a high-affinity receptor for all thrombin forms and acts as a cofactor for the thrombin-dependent activation of protein C.[43] The endothelial cell protein C receptor (EPCR) provides cell-specific binding sites for both protein C and activated protein C (APC).[44–47] When bound to thrombomodulin, thrombin's procoagulant activities (e.g., its capacity to generate fibrin and activate factor V, factor VIII, factor XI, and platelets) are neutralized, and the rate of inactivation of thrombin by antithrombin is increased.[48–50] The generation of APC by the thrombin–thrombomodulin complex leads to inactivation of the procoagulant cofactors factor Va and factor VIIIa, thus suppressing thrombin formation.[51,52] Thrombin–thrombomodulin, or the "protein Case" (see Fig. 125.4) complex, also has an antifibrinolytic role via activation of the fibrinolysis inhibitor, thrombin-activatable fibrinolysis inhibitor (TAFI; see reviews listed in the References[53–56]).

Thrombomodulin activity on the surface of endothelial cells is decreased by inflammatory cytokines,[57,58] and this decrease may contribute to the hypercoagulation characteristic of inflammatory states.

Soluble Plasma Procofactors

Factor V

Factor V is a large single-chain glycoprotein (GP) that circulates in human plasma (see Table 125.1 and Fig. 125.5B) and is also contained in the α-granules of human platelets, with approximately 18% to 25% of the total factor V found in platelets.[59] The procofactor factor V is proteolyzed by α-thrombin to the active cofactor factor Va.[60] Factor Va functions both as a factor Xa receptor and positive modulator of factor Xa catalytic potential in the prothrombinase complex (see Fig. 125.4).[61] Factor Va is proteolytically inactivated by APC.[62,63] The importance of this regulatory mechanism is demonstrated by the "APC resistance" syndrome associated with factor V$^{\text{Leiden}}$.[64,65] Individuals with factor V$^{\text{Leiden}}$ have a G to A substitution at nucleotide 1691 in the factor V gene that results in an Arg^{506}→Gln mutation at the protein level.[66] Factor Va$^{\text{Leiden}}$ has normal cofactor activity as part of the prothrombinase complex. However, unlike normal factor Va, factor Va$^{\text{Leiden}}$ is more slowly inactivated by APC. The Arg^{506}→Gln mutation hinders the first step in the series of inactivating cleavages by APC. Cleaved factor Va$^{\text{Leiden}}$ retains limited cofactor activity and continues to promote thrombin generation. The identification, role in coagulation, and overall importance of factor V in hemostasis have been described in numerous reviews.[61,67]

Factor VIII

The soluble procofactor factor VIII, or antihemophilic factor (see Fig. 125.5B), circulates in plasma in complex with the large multimeric protein vWF.[68] vWF acts to regulate the plasma concentration of factor VIII. Factor VIII interaction with vWF requires the NH_2- and COOH-termini of the factor VIII light chain (A3, C1, and C2 domains), although a specific vWF binding site has been identified at residues 1673–1684 on the light chain.[68–71] Factor VIII is activated by thrombin cleavage at three sites (Arg^{372}, Arg^{740}, Arg^{1689}) to generate the heterotrimeric cofactor factor VIIIa.[72] The vWF binding site is removed from the factor VIII protein by thrombin cleavage at Arg^{1689}. After forming, vWF–free factor VIIIa forms a complex with the serine protease factor IXa, Ca^{2+}, and a membrane (provided by platelets), resulting in the intrinsic tenase complex (see Fig. 125.4). Factor VIIIa function is downregulated by the relatively rapid dissociation of the noncovalently associated A2 subunit, which is produced by the cleavages required for activation, and by cleavage by APC.[52] Factor VIII is homologous (40% identity) to the procofactor factor V.[73]

Deficiency of factor VIII, or hemophilia A, is a well-characterized bleeding disorder linked to the X chromosome (see Chapter 134).[74] Hemophilia A therefore occurs almost exclusively in males at a frequency of 1 in 5000 to 1 in 10,000 individuals.[75]

von Willebrand Factor

vWF has several key roles in coagulation. It is synthesized in endothelial cells and also contained in the α-granules of human platelets.[76] vWF is a large adhesive GP that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers that range in size from dimers (M_r=600,000) to extremely large multimers of more than 20 million kDa. vWF has binding sites for factor VIII, heparin, collagen, platelet GPIb, and platelet GPIIb–IIIa.[77–90] vWF acts as the bridge between platelets to promote platelet aggregation. The primary platelet binding site for vWF is the GPIb–IX–V receptor complex (see Chapter 124). GPIb–IX–V is an active receptor on unstimulated platelets and serves to promote platelet aggregation and adhesion to vWF in the absence of platelet activation.[91]

vWF is a structural protein and is part of the subendothelial matrix. Endothelial cells secrete vWF multimers, which are larger than those found circulating in plasma.[92] The function of these large multimeric forms of vWF is to bind to and agglutinate blood platelets under high shear conditions. These large multimers of vWF are degraded by a specific metalloprotease called a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS)-13.[93–95] In familial and acquired thrombotic thrombocytopenic purpura, ultra-large vWF multimers are correlated with defective ADAMTS-13 activity (see Chapter 133).[96]

ABO blood type has a significant influence on vWF levels, with individuals of types A, B, or AB blood having much higher levels of vWF than those with type O blood.[97,98] vWF is also known for its role in ristocetin-induced platelet agglutination,[99,100] which is the basis of clinical assays for von Willebrand disease, a fairly common disorder that is estimated to occur in 1% to 2% of the general population (see Chapter 133).[101–104] vWF is also an acute-phase reactant, and vWF levels are elevated as a result of stress, pregnancy, or surgical trauma.[105–108]

The Intrinsic Accessory Pathway Proteins

The designation "intrinsic accessory pathway" emerged as the relationship between genetic deficiencies and bleeding phenotypes was established (see Fig. 125.1). Deficiencies of proteins associated with the intrinsic or accessory pathway (factor XII, prekallikrein, and high-molecular-weight kininogen [HMWK]) are not ordinarily associated with excessive bleeding, even after surgical challenge (see Chapters 121 and 135).[109–111] In contrast, deficiencies of the protein components of the extrinsic or primary pathway (prothrombin and factors V, VII, VIII, IX, and X) can lead to severe bleeding diatheses.[112–116] The physiologic role of the accessory pathway is therefore not clearly understood.[117]

Although the intrinsic pathway proteins have no defined role in normal hemostasis, these accessory pathway factors are thought to play a key role in disseminated intravascular coagulation associated with the systemic inflammatory response syndrome[118,119] and in the promotion of thrombus stability,[117,120,121] and may be a new target to control pathologic coagulation.[122] Also, the accessory pathway is important in cardiopulmonary bypass because of contact between blood components and synthetic surfaces.[119] Recent evidence suggests that biologic activation of the contact pathway system may be accomplished through assembly of these proteins on endothelial cell membranes and that prekallikrein is activated by an endothelial cell membrane cysteine protease rather than by factor XII.[123,124] Extracellular RNA derived from damaged or necrotic cells has also been found to participate in the activation of proteases of the contact pathway by providing a procoagulant cofactor template for factor XII- or XI-induced contact activation.[125] Polyphosphates, linear inorganic polymers of 60 to 100 phosphate residues, released from platelets have also been shown to activate fXII (see Chapter 121).[126]

In principle, factor XI represents an intersection point for the two pathways. Individuals with factor XI deficiency (hemophilia C) have a variable bleeding phenotype upon surgical challenge,[127,128] therefore establishing an essential role for factor XI in hemostasis (see Chapter 135). During the coagulation process, factor XIa formation appears to be catalyzed by thrombin as part of a positive-feedback loop stemming from thrombin generation.[129] Factor XIa then functions in the propagation phase of thrombin generation in association with the primary pathway by activation of factor IX.[130]

Three proteins, factor XII, prekallikrein, and HMWK, are required for activity of the intrinsic or accessory pathway. Factor XII and prekallikrein are zymogens that are activated to generate serine proteases, and HMWK is a nonenzymatic procofactor (Fig. 125.6). The activation of this pathway in vitro is accomplished when factor XII autoactivates to factor XIIa upon exposure to foreign surfaces, including kaolin, dextran sulfate, and sulfatides.[131–133] The substrates for factor XIIa, prekallikrein, and factor XI exist in noncovalent complex with HMWK and become activated to kallikrein and factor XIa, respectively.[134] Positive-feedback loops exist in which kallikrein cleaves HMWK, thereby releasing bradykinin and allowing more prekallikrein and factor XI to associate and activate.[135] This pathway is also negatively regulated by the cleavage of HMWK by factor XIa.[136]

Proteinase Inhibitors

Proteinases, enzymes that hydrolyze peptide bonds, are found in a wide array of biologic systems, including the blood coagulation

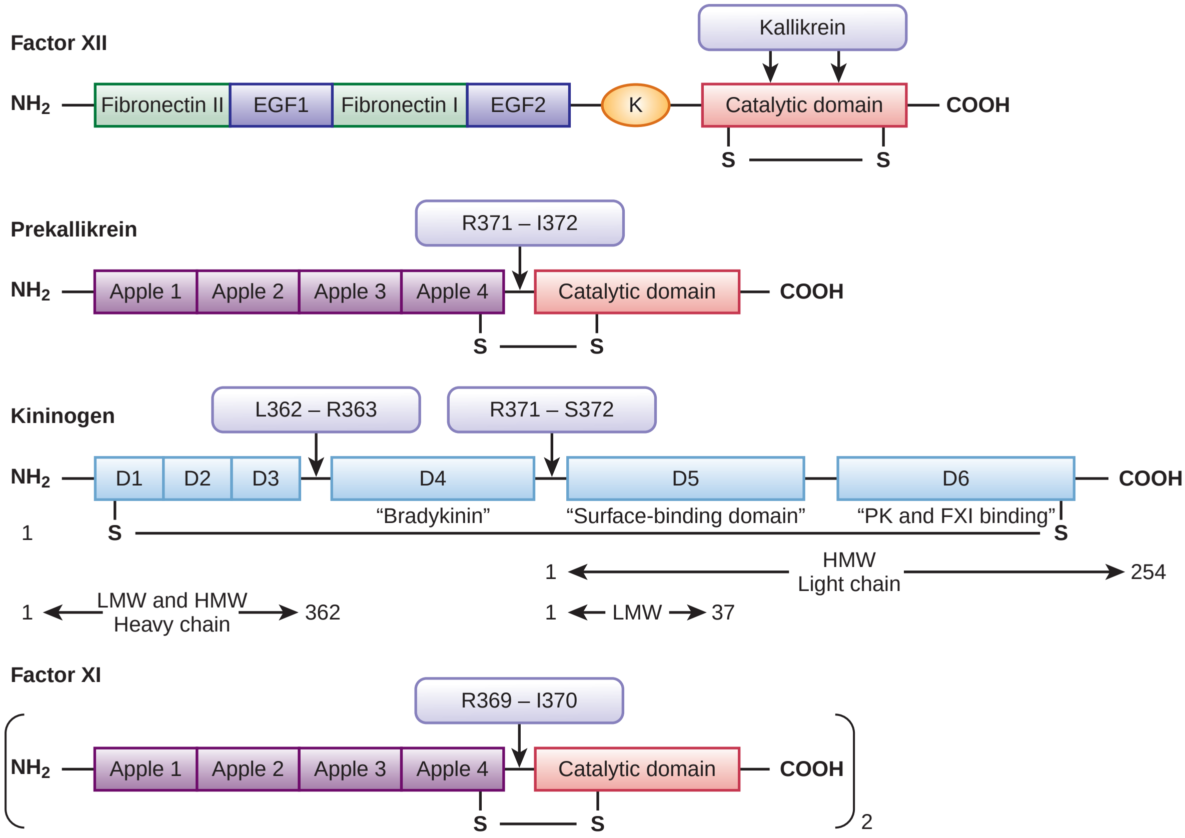

Figure 125.6 SCHEMATIC REPRESENTATION OF THE ACCESSORY PATHWAY (INTRINSIC) PROTEINS. Factor XII, prekallikrein, kininogen, and factor XI are shown with their various domains depicted. Cleavage sites for activation are identified with an arrow, and with the specific amino acid residues of the site shown. Key interchain disulfide bonds (-S-S-) are included. For the kininogens, horizontal arrows indicate the amino acid residues defining heavy and light chain regions of the activated forms of the cofactors. Factor XI is illustrated as a monomer. *EGF*, Epidermal growth factor; *FXI*, factor XI; *HMW*, high molecular weight; *LMW*, low molecular weight; *PK*, prekallikrein.

process (clot formation and fibrinolysis), digestive system, apoptotic cascades, and the immune system. To keep these systems in balance between activation and inhibition, a complex system of proteinase inhibitors has evolved. In blood, proteinase inhibitors constitute a significant percentage of circulating proteins. In general, proteinases that activate the coagulation and fibrinolytic cascades have highly defined substrate specificities. Coagulation is kept in check through the action of several specific and broad-spectrum proteinase inhibitors. Specific clot formation inhibitors are antithrombin, tissue factor pathway inhibitor (TFPI), heparin cofactor II, and protein C inhibitor. Together specific and broad-spectrum inhibitors function to localize, limit, and control hemostasis (see Chapter 121).

Antithrombin

Antithrombin is a member of the serpin proteinase inhibitory family and circulates in blood as a single-chain GP[137] (see Table 125.1; Fig. 125.7). Congenital antithrombin deficiency exhibits an autosomal dominant pattern of inheritance, with an incidence of 1 in 2000 to 1 in 5000.[138] Individuals with this deficiency have partial expression of antithrombin and are prone to venous thromboembolic disease.[139] The complete absence of antithrombin is lethal.

Antithrombin has a broad spectrum of inhibitory activity, with most of its target proteases participating in the coagulation cascade (see Fig. 125.1). It is primarily an inhibitor of the serine proteases thrombin, factor Xa, factor IXa, factor VIIa–tissue factor, factor XIa, factor XIIa, and kallikrein.[140–142] Heparin and heparan sulfate potentiate these reactions, and heparin is used for the prevention and treatment of thrombosis. When antithrombin is complexed with heparin, its rate of inhibition of several coagulation proteases is accelerated by up to 10,000-fold. The general mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure (the reactive center loop) of antithrombin, forming a tight, equimolar (1:1) complex. Inactivation proceeds through covalent bond formation between antithrombin and the protease followed by inactivating structural rearrangements of both antithrombin and the protease.

Antithrombin also displays antiproliferative and anti-inflammatory properties that primarily derive from its ability to inhibit thrombin. In addition, latent or cleaved forms of antithrombin have antiangiogenic activities.[143]

Tissue Factor Pathway Inhibitor

TFPI, formerly called *extrinsic pathway inhibitor* or *lipoprotein-associated coagulation inhibitor*, is a multivalent Kunitz-type plasma proteinase inhibitor. It circulates in plasma as a heterogeneous collection of partially proteolyzed forms (see Table 125.1 and Fig. 125.7).[144–147] Up to 90% of circulating TFPI is found associated with lipoproteins, primarily low-density lipoprotein.[144,148,149] Parenteral TFPI is cleared from the circulation mainly by the liver and has an unusually short half-life (minutes) compared with other proteinase inhibitors.

Many reviews of TFPI have been published.[150–160] The importance of TFPI in blood coagulation is best illustrated through transgenic mice with complete TFPI deficiency; the deficiency is embryonically lethal.[154] However, this lethality in mice can be rescued by heterozygous or homozygous factor VII deficiency.[161] This implies that diminishing the level of factor VII lessens the need for TFPI-mediated inhibition of the factor VIIa–tissue factor coagulation pathway during embryogenesis.[161] Similarly, the combination of low normal TFPI with factor V Leiden is lethal.[162,163] Mice with combined heterozygous TFPI deficiency and homozygous apolipoprotein E deficiency develop more extensive atherosclerosis burden,[164] raising the possibility that TFPI contributes to protection from atherosclerosis, as well as serving as a regulator of thrombosis.

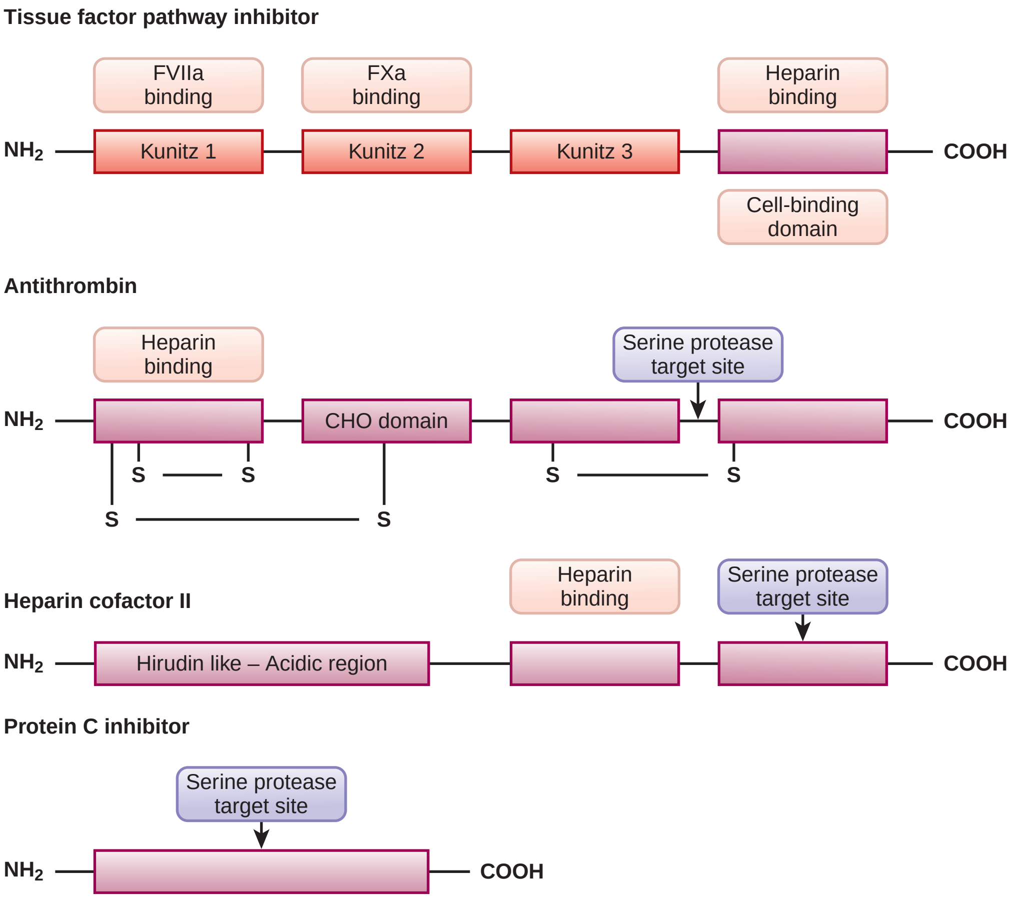

Figure 125.7 SCHEMATIC REPRESENTATION OF SEVERAL PROTEINASE INHIBITORS. Tissue factor pathway inhibitor (TFPI) contains three Kunitz domains. TFPI inhibits the serine proteases FVIIa and FXa, shutting down the extrinsic pathway of coagulation. Kunitz 1 domain binds FVIIa, and Kunitz 2 domain binds FXa. The COOH-terminus of TFPI contains a basic region, the cell-binding domain, which binds to heparin. Antithrombin (AT) contains two intrachain disulfide bonds (-S-S-) in its NH_2-terminus and one in its COOH-terminus with a carbohydrate-rich domain (CHO) in between. The region of interaction between the active sites of target proteases and AT is illustrated (reactive center loop). Heparin binding to AT occurs in the NH_2-terminus and enhances the rate of inhibition of serine proteases. Heparin cofactor II inhibits thrombin. Structurally, the inhibitor contains an NH_2-terminus hirudin-like region, a heparin or dermatan sulfate binding region, and a reactive center loop. The reactive site is at Leu^{444}. Protein C inhibitor is a serine protease inhibitor that inhibits several proteases, including activated protein C, thrombin, and FXa. It is also a potent inhibitor of the thrombin–thrombomodulin complex. The reactive bond (Arg^{354}) in the reactive center loop is shown. *FVIIa*, Factor VIIa; *FXa*, factor Xa.

TFPI is the principal stoichiometric inhibitor of the extrinsic factor tenase complex (factor VIIa–tissue factor).[165] Effective TFPI inhibition of the factor VIIa–tissue factor complex depends on the presence of factor Xa. Thus inhibition of the extrinsic factor tenase by TFPI occurs only after significant factor IXa and factor Xa formation. Inhibition by TFPI is achieved by formation of the stable quaternary, by tissue factor–factor VIIa–TFPI–factor Xa complex, and by formation of the factor Xa–TFPI complex directly.

Heparin Cofactor II

Heparin cofactor II is a member of the serpin family (see Fig. 125.7). The plasma concentration of heparin cofactor II is 0.5 to 1.4 μmol/L[166,167] (see Table 125.1). Its plasma half-life is approximately 2.5 days. Similar to antithrombin, heparin cofactor II inhibits thrombin in a reaction that is accelerated more than 1000-fold by heparin.[168] However, unlike antithrombin, the only coagulation enzyme inhibited by heparin cofactor II is thrombin.[169] The rate of thrombin inhibition by heparin cofactor II—in the absence or presence of heparin or heparin-like molecules—is significantly slower than by antithrombin under similar conditions. Considering that the plasma concentration of heparin cofactor II is 25% to 50% that of antithrombin and that low levels of heparin cofactor II are not strongly associated with thrombosis,[170] the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned.

In vitro, heparin cofactor II inhibition of thrombin is accelerated by dermatan sulfate proteoglycans synthesized by fibroblasts and vascular smooth muscle cells.[171] Thus, heparin cofactor II may be uniquely suited to regulate extravascular thrombin in areas of vascular endothelium disruption in which heparin cofactor II would be exclusively stimulated by dermatan sulfate in the subendothelium. In addition, heparin cofactor II may participate in regulation of acute inflammation and wound healing by harboring a peptide chemotactic for neutrophils and monocytes that is released by leukocyte proteolysis.[172]

Heparin cofactor II may also have a role in protection from thrombosis during pregnancy. Increased levels of dermatan sulfate in the maternal and fetal circulation[173] along with increased levels of heparin cofactor II in pregnant women have been reported.[174,175] Low levels of thrombin–heparin cofactor II complexes are detected in normal plasma samples; elevated levels were detected in patients with disseminated intravascular coagulation.[176] Although inherited deficiency of heparin cofactor II has been associated with thrombosis, this is not always the case.[177–179]

Protein C Inhibitor

Protein C inhibitor is a member of the serine proteinase inhibitor family and is also known as *plasminogen activator inhibitor-3* (PAI-3). It circulates in blood at a concentration of 5 μg/mL[180,181] (see Table 125.1 and Fig. 125.7) and is cleared from the circulation with a half-life of 1 day. When in complex with a target (e.g., APC), it is cleared from circulation with a $t_{1/2}$ of 20 minutes.[182]

Protein C inhibitor is considered a nonspecific inhibitor in that its targets range from procoagulant (serine proteinases), anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen.[183,184] The major target of protein C inhibitor, as its name suggests, appears to be APC.[182,185,186] Protein C inhibitor has been shown to regulate TAFI activation by inhibiting the thrombin–thrombomodulin complex.[187] Its importance as a dual regulator of coagulation and fibrinolysis remains unresolved.[188,189] Other targets for protein C inhibitor include human plasma kallikrein,[190] factor XIa,[190] factor Xa, and thrombin. Because there are no documented patients with a deficiency to date, the actual function of protein C inhibitor in vivo has yet to be elucidated.

α_2-Macroglobulin

α_2-Macroglobulin is a nonspecific proteinase inhibitor that targets a broad spectrum of protease substrates. It is present in human plasma at concentrations ranging from 2 to 4 μmol/L (2 to 3 mg/mL). α_2-Macroglobulin can also be found at higher concentrations in extravascular fluids.[191] This protease inhibitor can be produced in a variety of cells, including hepatocytes, fibroblasts, and macrophages.[192,193] Human α_2-macroglobulin circulates in plasma as a tetramer.[191–198] α_2-Macroglobulin has a unique mechanism of action, which accounts for its broad specificity. The initial step involves the "bait region" of α_2-macroglobulin.[199] After proteolysis in this bait region, α_2-macroglobulin undergoes conformational changes that trap the proteinase inside the molecule.[199] Consequently, α_2-macroglobulin inhibits a broad range of proteinases. It is distinctive in its capacity to inhibit members from each of four mechanistic classes of proteinases (serine, cysteine, and aspartic proteinases, and metalloproteinases). α_2-Macroglobulin functions as a secondary inhibitor of serine proteinases in plasma by inhibiting thrombin, kallikrein, and plasmin.[200,201] It may also be important in preventing thromboembolic events when there is a congenital deficiency of antithrombin or acquired deficiency in sepsis.[202,203] α_2-Macroglobulin also inhibits various growth factors and cytokines, including transforming growth factor-α (TGF-α),[204] interleukin (IL)-1β,[205] IL-6,[206] acidic fibroblast growth factor,[207] basic fibroblast growth factor,[207] tumor necrosis factor-α (TNF-α),[208] and IL-2.[209] Polymorphisms identified in α_2-macroglobulin have been thought to play a role in Alzheimer's disease.[210–212] Overall, the biologic role of α_2-macroglobulin in vivo is still being elucidated.

Reduced levels of α_2-macroglobulin in humans have been observed in individuals with chronic obstructive lung disease[213] and metastatic cancer.[214] Complete deficiency has not been reported, suggesting that absence of α_2-macroglobulin is incompatible with survival. Inactivation of the α_2-macroglobulin gene in mice has no obvious phenotype, but the mice are resistant to endotoxin challenge.[215] It has been suggested that α_2-macroglobulin serves as a neutralizer of TGF-α and an inducer of nitric oxide synthesis in mice.[216]

Endothelium

Blood cells and the vasculature are crucial to normal hemostasis. Multiple processes involving components of the vessel wall, circulating platelets, and plasma protein moieties interact to maintain blood fluidity (see Chapter 122). These must be precisely choreographed to allow the vasculature to perform its myriad complex physiologic activities (Fig. 125.8). The endothelium, the thin layer of cells that lines the interior of blood and lymphatic vessels, plays a key role because of its strategic interface among organs, tissues, and circulating blood. The cells that form the endothelium are called *endothelial cells*, those in direct contact with blood are called *vascular endothelial cells*, and those in direct contact with lymph are known as *lymphatic endothelial cells*. Vascular endothelial cells line the entire circulatory system (from the heart to the capillaries).

The endothelium varies in morphology and physiologic function in different parts of the vasculature (see Chapter 122). This complex cellular network not only provides a structural barrier to contain flowing blood but also regulates blood pressure, vascular tone, permeability, and processes involving other cells such as smooth muscle cells, leukocytes, and platelets, and deposits an intricate basement membrane and extracellular matrix.[217] In addition, the endothelium is involved in inflammatory and immune responses and angiogenesis. [218] Defects in vascular endothelium function, therefore, have profound physiologic implications. Excessive bleeding can result from structural abnormalities of the endothelial cell layer or supporting matrix. Impaired expression or secretion of PAI-1 by the endothelium likewise promotes bleeding through increased fibrinolytic activity.[219] Conversely, endothelial cells are also involved in mediating processes that promote atherosclerotic plaque formation and thrombotic pathologies.[220]

The early work of Ware and Seegers[221] identified the phospholipid requirements for coagulation. The biologic elements contributing to the phospholipid include damaged vascular tissue, activated platelets, and inflammatory cells. The contributions of the membrane to the formation and expression of procoagulant complexes are essential. However, the nature of the membranes that support procoagulant reactions is poorly understood. Mechanically damaged cells can provide the anionic membrane bilayer inner leaflet phospholipids, which can support general procoagulant complex formation; however, more subtle cellular activation events also generate selective complex-forming sites on intact cells. Activated platelet membranes express individual binding sites for the factor IXa–factor VIIIa and factor Xa–factor Va complexes. Hemorrhagic pathology is therefore associated with thrombocytopenia and is also displayed in a rare disease, Scott syndrome, which appears to result from the improper presentation of these platelet binding sites (see Chapter 124).[222] Binding sites have also been reported on several peripheral blood cells, especially activated monocytes. The vascular endothelium itself can provide binding sites after stimulation by cytokine growth factors.[223] The endothelium also provides the anticoagulant thrombomodulin, TFPI and heparan sulfate. EPCR provides cell-specific binding sites for both protein C and APC.[44,224] EPCR is downregulated by TNF-α.[44] Monocytes appear to express specific binding sites for APC that are distinct from the EPCR.[225] The cell-expressed binding sites may be important in the anti-inflammatory properties of APC.[46]

A further consequence of damage to the endothelium is the release of pathologic quantities of vWF, which promote platelet aggregation and adhesion to the subendothelium, and thus the formation of potentially fatal thrombi. Endothelial dysfunction is also linked with hypertension, diabetes, obesity, and hyperlipidemia.

Platelets

Platelets, or thrombocytes, are vital to procoagulant events and contribute to the fibrinolytic process as well. They are small, irregularly shaped, clear cell fragments, which are derived from megakaryocytes (see Chapter 123). The average lifespan of a platelet is approximately 5 to 9 days. Platelets are at the balance of bleeding or clotting events: when platelet numbers are low (thrombocytopenia), excessive bleeding can occur, and when platelet numbers are high (thrombocytosis), thrombosis can occur. Disorders that reduce the number of platelets but typically cause thrombosis instead of bleeding are heparin-induced thrombocytopenia and thrombotic thrombocytopenic purpura (see Chapters 131 and 132).

Like the endothelium, the undisturbed platelet presents a nonthrombogenic surface. Important components of platelet physiology are surface adhesion protein complexes and the platelet secretory granules: α-granules, lysosomes, and dense granules (see Chapter 124). Contents of the α-granules include procoagulant and adhesive proteins such as fibrinogen, fibronectin, thrombospondin, vWF, P-selectin, HMWK, platelet factor 4, osteonectin, factor V,[59] and factor XI.[226] Other α-granule contents, α_1-antitrypsin, protein S, TFPI, and platelet inhibitor of factor XI, are involved in anticoagulant activities.[227–229] The α-granule also contains proteins that meditate both pro- and antifibrinolytic processes. These proteins include plasminogen, α_2-antiplasmin, factor XIII, and PAI-1.[230–234] In the unstimulated platelet, the granule contents remain internalized and anionic phospholipid is sequestered in the inner leaflet of the plasma

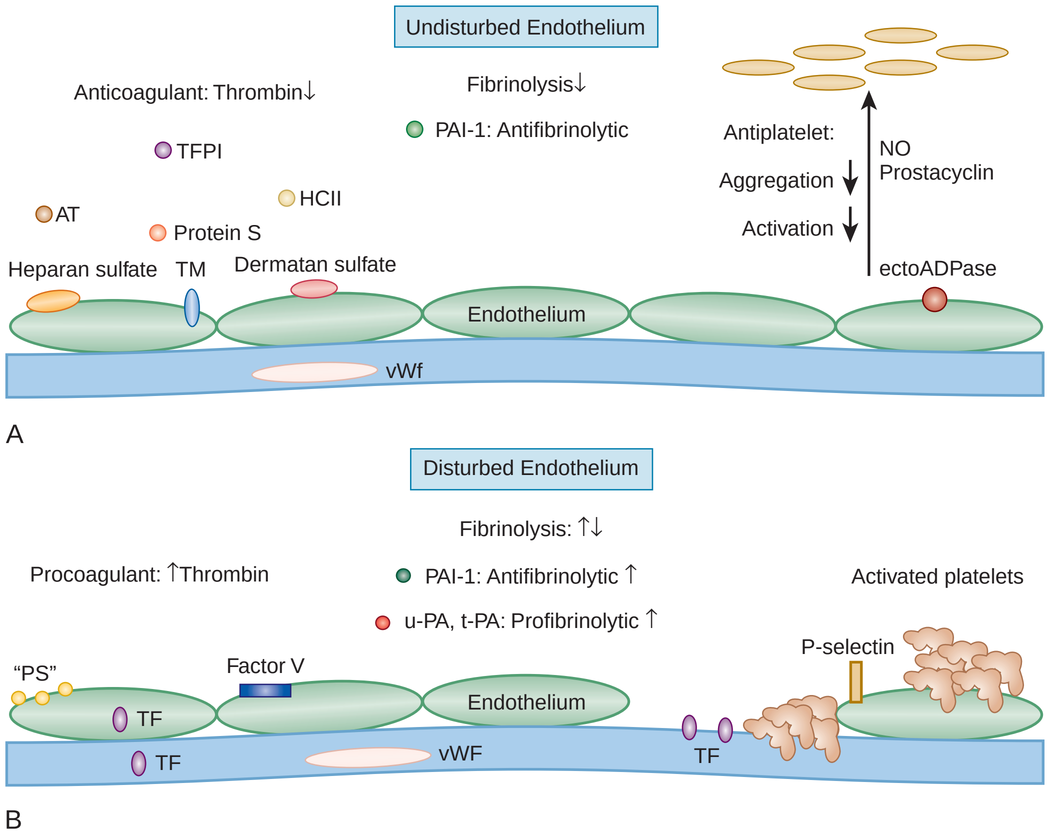

Figure 125.8 SCHEMATIC OF THE CHANGES THAT OCCUR TO THE ENDOTHELIUM UPON INJURY. Under normal conditions in the absence of injury or chemical stimulus (A), *the undisturbed endothelium* actively downregulates thrombin generation through the production of tissue factor pathway inhibitor (TFPI), antithrombin (AT), protein S, heparan sulfate, thrombomodulin (TM), and dermatan sulfate. The undisturbed endothelium is also antifibrinolytic and secretes plasminogen activator inhibitor-1 (PAI-1). In the absence of a stimulus, the endothelium likewise prevents platelet activation, secretion, and aggregation through the production of nitric oxide (NO), prostacyclin, and the membrane-associated protein ectoADPase. When the *endothelium is disturbed* (B), the endothelium becomes procoagulant and accelerates thrombin formation by exposing or expressing anionic phospholipid ("PS"), tissue factor (TF), and factor V. The fibrinolytic response is modulated by the release of both antifibrinolytic and profibrinolytic molecules. Urokinase plasminogen activator (u-PA) and tissue plasminogen activator (t-PA) are profibrinolytic and serve to activate plasminogen; PAI-1 inhibits both enzymes and is antifibrinolytic. Platelet activation, secretion, and aggregation are also promoted under conditions in which the endothelium is disrupted. von Willebrand factor (vWF) in the subendothelial matrix is exposed, allowing platelets to attach to the surface of the vessel. P-selectin likewise promotes platelet attachment.

membrane. Prostaglandin I2 (prostacyclin) and nitric oxide released from endothelial cells, the presence of CD39, and the inability of normal plasma vWF to bind spontaneously to the platelet surface are the inhibitory mechanisms that keep platelets unactivated.[235]

When the vascular system is perturbed, platelet plug formation occurs in stages. During the first stage, platelets adhere and are activated by exposure to collagen and vWF and other matrix components (Fig. 125.9). The cytoskeleton spreads and platelet–fibrinogen aggregates are formed, and the contents of the granules are secreted.[236–238] The activated platelets adhere to each other, endothelial cells, leukocytes, and components of the subendothelial matrix.[239] The phosphatidyl serine–rich internal face of cell membranes are exposed and present a highly procoagulant surface to the circulation.[240] In addition, activated platelets express specific receptors or binding sites for the assembly of the procoagulant multiprotein complexes (Fig. 125.10). There are approximately 3000 factor Va binding sites on the activated platelet membrane.[241] Factor Va forms part of the receptor for factor Xa. Factor Xa is also reported to bind to effector cell protease receptor-1 (EPR-1) molecules expressed on activated platelets.[241–244]

In the extension phase of platelet plug formation, where activated platelets accumulate on top of the initial monolayer of platelets bound to collagen, the presence of receptors on the platelet surface allows agonists such as thrombin, adenosine diphosphate, and thromboxane A_2 to recruit additional circulating platelets into the growing hemostatic plug (see Fig. 125.10). Subsequently, during the platelet plug formation perpetuation phase, close contacts between platelets promote the growth and stabilization of the hemostatic plug, in part through contact-dependent signaling mechanisms.[235]

Clot Proteins

A central event in blood coagulation is the conversion of soluble fibrinogen (factor I) to insoluble fibrin (see Fig. 125.1; see reviews listed in the References[245,246]). Fibrinogen functions in hemostasis to stem blood loss. It serves as a molecular bridge to support interplatelet aggregation, and it is the precursor of fibrin, which is the main component of the protein scaffolding of the forming hemostatic plug. Platelet aggregation critically depends on fibrinogen binding to activated platelets via the platelet fibrinogen receptor GPIIb/IIIa as well as fibrin adhesion (see Fig. 125.10). Fibrinogen/fibrin also regulates thrombin activity by interactions that include the proteolytic cleavage by thrombin of fibrinopeptides[247,248] to form a fibrin clot and thrombin exosite binding to fibrin, which potentially limits the diffusion of thrombin, thereby regulating clot propagation. The structure, stability, and duration of insoluble fibrin are controlled by an interplay between fibrin formation and fibrinolysis, which includes other molecular and cellular components.

The description of fibrinogen activation and fibrin assembly has been based on studies using citrated plasmas or purified proteins. The

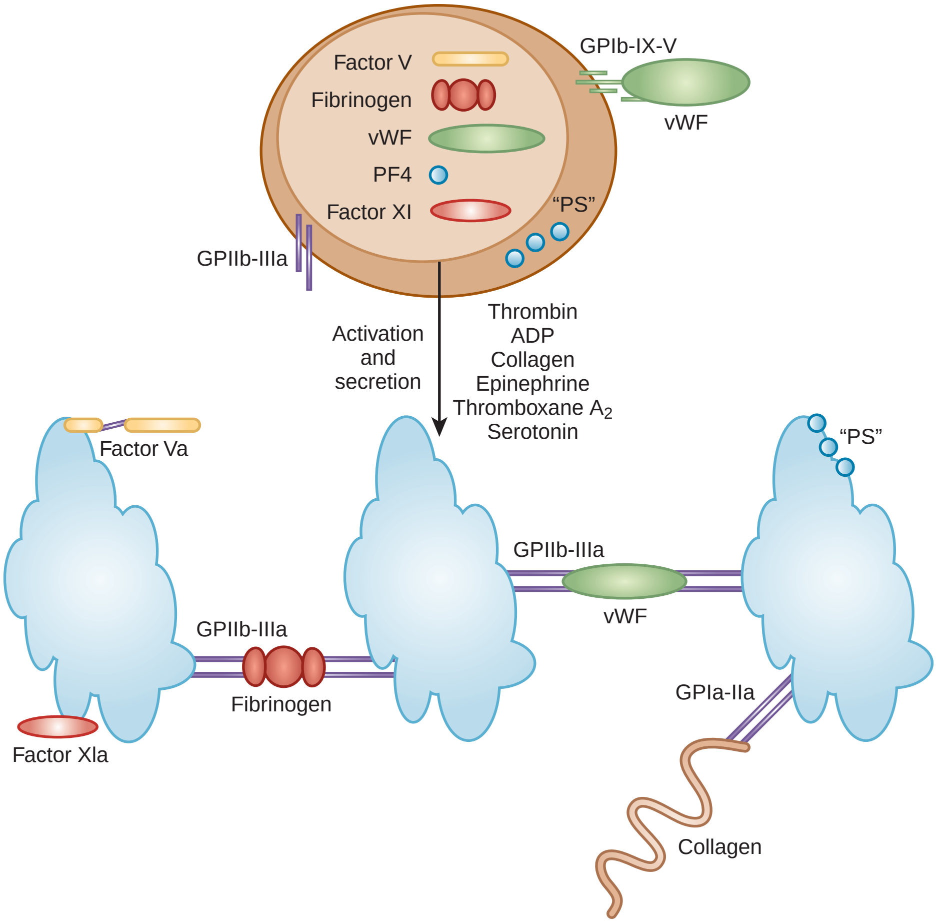

Figure 125.9 SCHEMATIC OF PLATELET ACTIVATION, SECRETION, AND AGGREGATION. Platelets have multiple functions in hemostasis. They serve as reservoirs of factor V, fibrinogen, von Willebrand factor (vWF), platelet factor 4 (PF4), and factor XI. Platelets also contribute a significant portion of the anionic phospholipid ("PS") necessary for membrane-dependent complex formation and function. In the unstimulated state, proteins and other molecules are sequestered in the platelet granules. Anionic phospholipid is found only in the inner leaflet of the platelet membrane and is not exposed to flowing blood. The GPIb–IX–V complex, which recognizes vWF, is an active receptor, but the GPIIb/IIIa receptor, which recognizes a variety of molecules, including fibrinogen and vWF, is not active. The GPIb–IX–V receptor likely allows unstimulated platelets to attach to exposed subendothelial vWF, thereby promoting procoagulant events before platelet activation. Upon activation by a variety of agonists, platelets secrete granule contents, become activated and bind factor V/Va and factor XI/XIa, and expose anionic phospholipid. The GPIIb/IIIa receptor serves to link platelets to each other and the vessel wall. Collagen receptors, such as GPIa–IIa, promote both platelet activation and aggregation. *ADP*, Adenosine diphosphate; *GP*, glycoprotein.

three main players in fibrinogen to fibrin conversion are the enzyme thrombin, the substrates fibrinogen, and the cross-linking transglutaminase factor XIII. Fibrinogen is composed of six polypeptide chains (two Aα, two Bβ, and two γ chains) that form two symmetrical half molecules (three chains each) with the NH_2-termini cross-linked to each other. The outside two domains of fibrinogen are composed of the Bβ and γ chains, and designated as the D domain. The central domain that contains the NH_2-termini of all the chains is designated as the E domain. From x-ray crystallographic data, fibrinogen has a trinodular structure aligned as D–E–D domains (Fig. 125.11).

The kinetics of fibrinogen cleavage by thrombin results in the hydrolysis of Arg–Gly bonds removing small, polar N-terminal fragments (fibrinopeptides [FPs]) from the NH_2-terminal of the Aα and Bβ chains Fig. 125.11.[249,250] Cleavage at the Arg–Gly bond of the Aα chain releases FPA and forms fibrin I. The release of two FPA peptides exposes a site in the E domain that interacts with a site in the D domain to form overlapping fibrils. Subsequent cleavage of the Arg–Gly bond on the Bβ chain releases FPB to form fibrin II, presumably increasing lateral aggregation of the protofibrils.[251]

An important enzyme for the structure and stability of the fibrin clot is transglutaminase factor XIIIa.[252–254] Its function is to cross-link fibrin and other adhesive proteins, including integrin receptors, providing a stable network. Only the Aα chain and the γ chain, which have donor (Gln) and acceptor (Lys) sites, participate in cross-linking of adjacent glutamyl and lysyl residues by factor XIIIa.[251,255–257]

Fibrinogen is also required for competent inflammatory reactions. Fibrinogen is an acute-phase reactant whose levels increase during inflammation.[258,259] In these situations, fibrinogen functions as a bridging molecule in cell-cell interactions.[260,261] Fibrin and fibrinogen constitute a matrix that modulates cellular responses in a variety of cell types, including endothelial cells, epithelial cells, leukocytes, platelets, and fibroblasts. Cellular receptors that bind fibrinogen and fibrin include the integrins $\alpha_{IIb}\beta_3$, $\alpha_V\beta_3$, and $\alpha_5\beta_1$, and the cellular adhesion molecules intercellular adhesion molecule-1 and vascular endothelial cadherin.[262–265]

Fibrin clot-based assays have been extensively used in the clinical diagnosis of bleeding disorders (see Chapter 127). Two in vitro plasma tests, the PT[266,267] and the activated partial thromboplastin time (aPTT),[268] segregate the coagulation process into tissue factor–initiated or surface contact processes, respectively. The aPTT, which initiates coagulation by the introduction of a foreign surface, only examines the biologic constituents intrinsic to plasma. This assay is sensitive to isolated or combined deficiencies of factor XII, HMWK, prekallikrein, factor XI, factor VIII, factor IX, factor X, factor V, prothrombin, and fibrinogen. The PT assay is based on initiating coagulation via an extrinsic source of tissue factor (thromboplastin). The

Figure 125.10 SELECTED PLATELET RECEPTOR TARGETS AND THEIR RESPECTIVE INHIBITORY AGENTS. When a platelet encounters a break in the endothelium, it encounters molecules that trigger its activation, such as collagen, thromboxane A_2 (TXA_2), ADP, and thrombin. The ability of platelets to adhere, aggregate, respond to agonists, aid in coagulation, and bind fibrin are all processes mediated by the plasma membrane glycoproteins (GPs) of the platelet. The platelet GPIbIX–V constitutes the receptor for von Willebrand factor (vWF). GPIa/IIa mediates platelet–collagen interactions. GPIIb/IIIa is a receptor for fibrinogen. $P2Y_{12}$ is a chemoreceptor for ADP. The α_2A-adrenergic receptor (α_2A-AR) is expressed on platelets and binds the naturally occurring ligand epinephrine. Cyclooxygenase-1 (COX-1) is responsible for the formation of prostaglandins and thromboxane. COX-1 converts arachidonic acid to prostaglandin G_2 (PGG_2). Aspirin irreversibly inhibits COX-1. *TX*, Thromboxane; *TXA_2R*, thromboxane A_2 receptor.

Figure 125.11 SCHEMATIC REPRESENTATION OF WHOLE-BLOOD FIBRIN FORMATION. At the start of clot formation, thrombin simultaneously acts on fibrinogen (D–E–D) and factor XIII (FXIII). A portion (≈40%) of fibrinopeptide A (FPA) is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent fibrin molecules. Activated factor XIIIa (FXIIIa) simultaneously cross-links adjacent D domains (D=D). Thus, the initial soluble fibrin clot is composed of fibrinogen, fibrin, and γ–γ dimers with fibrinopeptide B (FPB) still attached. The initial clot is continuously acted on by thrombin, resulting in the release of the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The released FPB is selectively acted on by a carboxypeptidase B–like enzyme (CPB; potentially activated thrombin-activatable fibrinolysis inhibitor a), which cleaves the C-terminal arginine to produce des-Arg FPB. The significance of this cleavage is still unclear. *(From Brummel KE, Butenas S, Mann KG. An integrated study of fibrinogen during blood coagulation. J Biol Chem. 1999;274:22862, with permission.)*

PT assay is sensitive to isolated or combined deficiencies of factor VII, factor X, factor V, prothrombin, and fibrinogen. Although these in vitro clotting assays help establish a basis for hemostasis, abnormal test results are not always mirrored by human pathology associated with bleeding or thrombosis.

Fibrinolysis Proteins

Clot formation is integrated with clot dissolution (fibrinolysis). Fibrinolysis, the elimination of blood clots, has two types, primary fibrinolysis, and secondary fibrinolysis. Whereas primary fibrinolysis is a normal body process, secondary fibrinolysis is the breakdown of clots caused by a medicine, a medical disorder, or some other cause.

The biochemical mechanisms of clot dissolution center on fibrin-specific activation of plasminogen to plasmin. The key proteins involved are plasminogen, the tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), and the inhibitors (PAI-1, α_2-antiplasmin, and TAFIa). Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation (Fig. 125.12).[269] The process of plasminogen activation can occur through three distinct pathways: (1) the intrinsic activator system (analogous to the contact system of blood coagulation), (2) the extrinsic activators (t-PA and u-PA), and (3) an exogenous activator system involving pharmacologic agents (fibrinolytic drugs). The primary pathway used in vivo appears to be the extrinsic pathway. However, both the intrinsic as well as exogenous activator systems can play important roles in human disease.

t-PA and u-PA, secreted by the endothelium, have unique structures and properties that affect the specificity and rate of plasmin generation (see Fig. 125.12).[270] After being generated, plasmin digests fibrin in a pattern that produces a collection of degradation products, including fragment X, fragment Y, and the core fragments, fragments D and E. The first step in degrading fibrin is the removal of the α chains, thus exposing the coiled coils. As these coils are cleaved, different-sized fragments are released.[271] Fibrinogen is represented as a trinodular structure (D–E–D domains) with each E domain and D domain separated by a coiled coil domain. Upon formation of fibrin,

Figure 125.12 SCHEMATIC OF FIBRINOLYTIC PROTEINS. Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. The domain structure of human plasminogen is represented by Kringle domains (K1–K5), a catalytic domain, and the arrows indicate the sites of proteolytic cleavage by plasmin and plasminogen activators (tissue plasminogen activator [t-PA] and urokinase plasminogen activator [u-PA]). Disulfide bonds are illustrated by -S-S-. t-PA is a serine proteinase and consists of an A and B chain. The A chain consists of a fibronectin finger-like domain, an EGF-like domain, and two kringle domains. The K2 domain and the finger domain of t-PA mediate the binding of t-PA to fibrin. The B-chain of t-PA contains the active site catalytic triad. Single-chain t-PA is an efficient plasminogen activator in the presence of fibrin and is converted to the two-chain form by cleavage of the peptide bond between R275 and I276. This cleavage is performed primarily by the action of plasmin during fibrinolysis. Single-chain u-PA (sc-uPA) is a serine protease and is an ineffective catalyst. Plasmin or plasma kallikrein can hydrolyze the K158–I159 peptide bond, converting sc-uPA into the fully active two-chain form (two-chain u-PA) composed of an epidermal growth factor (EGF) domain (EGF), a single kringle domain, a connecting peptide region, and the serine protease-type catalytic domain. Thrombin-activatable fibrinolysis inhibitor (TAFI): Activation of TAFI (TAFIa) yields an exopeptidase with carboxypeptidase B-like substrate specificity. TAFIa delays fibrinolysis by cleaving COOH-terminus Arg or Lys residues made available during partial plasmin digestion of the fibrin clot. Removing these residues attenuates the self-amplifying mechanism of fibrin-based plasmin formation wherein partial plasmin proteolysis of fibrin increases the number of binding sites (COOH-terminal lysine residues) available for efficient plasminogen activation. TAFI contains an activation peptide region and a carboxypeptidase domain. It is activated by the thrombin–thrombomodulin complexes (IIa/TM) and plasmin–glycosaminoglycan complexes (Plm/GAG) by hydrolysis of the R92–A93 bond.

cross-links occur between alternating molecules of fibrin at the D domain (D=D). Plasmin degrades fibrin, releasing various-sized fragments, the smallest of which is the D=D or D-dimer (M_r=180,000). The largest of these fragments is XXD, X=D–E–D, with a mass of 595,000.[272,273] Elevated levels of D-dimer are found in the blood of patients with various thrombotic and thrombolytic disorders (see Chapter 127).[274] These circulating fragments are cleared by other proteases or by the kidney and liver.

Inhibitors of the Fibrinolytic System

Plasminogen activation in blood is primarily inhibited by PAI-1, which targets u-PA and t-PA. PAI-1 also has a role in tissue remodeling by interfering with vitronectin-dependent processes of cell adhesion and migration.[275] Congenital deficiency of PAI-1 is rare, with homozygous individuals displaying abnormal bleeding in response to trauma.[276] Platelets contribute to the fibrinolytic process by binding t-PA and plasminogen and supporting plasmin generation. Increased levels of plasma PAI-1 delay fibrin removal by shortening the functional lifetime of plasminogen activators, thereby shifting hemostasis to a more thrombotic state.[277]

TAFI is a plasma zymogen with homology to procarboxypeptidases A and B (see Fig. 125.12).[55,278–280] Activation of TAFI yields the exopeptidase (TAFIa) with carboxypeptidase B–like substrate specificity. TAFIa catalyzes the removal of basic amino acids (arginine, lysine) from the COOH-termini of polypeptides. The activation of many of the cofactors and zymogens of the coagulation and fibrinolytic cascades results in the generation of functional proteins with COOH-terminus arginine or lysine residues. COOH-terminus lysine residues that appear in fibrin fragments degraded with plasmin have been identified as the major substrates for TAFIa. The physiologic activator of TAFIa is the thrombin–thrombomodulin complex, thus defining TAFIa as a coagulation-dependent activity.[281] Because TAFIa functions as an attenuator of fibrinolysis,[53] an adequate rate of TAFIa generation appears critical for the stabilization of the blood clot. Plasmas with specific deficiencies in the coagulation pathway exhibit reduced rates of thrombin production, decreased levels of TAFIa, and premature clot lysis.[257,282,283]

Fibrinolytic drugs are often given after a myocardial infarct or ischemic stroke to dissolve the fibrin clot blocking the coronary or cerebral artery (see Chapters 144, 145, and 146). Fibrinolytic drugs are also used in massive pulmonary embolism (see Chapter 140). Antifibrinolytics, such as aminocaproic acid (ε-aminocaproic acid) and tranexamic acid, are used as inhibitors of fibrinolysis.

CONNECTIVITY AND DYNAMICS IN HEMOSTASIS

In the healthy state, the hemostatic system is relatively quiescent, with the vascular endothelial cells, the blood, and the extravascular tissue functioning to maintain fluidity. Blood platelets remain in a quiescent state because of the endothelial cell lining of the blood vessel being an active anticoagulant that secretes small molecules and enzymes. The endothelium also provides constituent anticoagulant proteins, which inhibit the blood coagulation system. These vascular anticoagulant systems are both passive and dynamic in nature, and function in cooperation with plasma components. The blood supplies pro- and anticoagulant proteins in the plasma and platelets, which contribute to the coagulation reaction. If the endothelium becomes damaged, the pro- and anticoagulant levels become imbalanced, and cells that should remain in the blood can leak through blood vessels into adjacent body tissue, which triggers a response. The dimensions of the response are relevant to the injury. The extravascular compartment and blood interact to rapidly produce a vigorous local coagulation response, which attenuates blood loss and initiates the vascular repair process in four phases: initiation, propagation, termination, and elimination/fibrinolysis.[284–286]

Initiation

If vascular injury occurs, a measured response is triggered in that the extent of damage regulates platelet and fibrin deposition. Activated platelets provide the membrane surfaces upon which coagulation enzymes can be anchored, assembled, and expressed. Therefore, the activated platelet membrane provides both an initiating and limiting component to the extent of a coagulation reaction.[287] More vascular damage produces more anchored activated platelets, and more membrane allows the assembly of more coagulation enzymes, which ultimately results in increased fibrin formation.

When the vascular system is perturbed, the initial stages of the hemostatic response are triggered. The initial principal player is the extrinsic tenase complex (tissue factor–factor VIIa), which is composed of a cell membrane; tissue factor exposed by vascular damage or cytokine stimulation; Ca^{2+}; and the serine protease plasma factor VIIa, which is already present in its active form at 1% to 2% of the factor VII zymogen concentration (Fig. 125.13).[53,288] Before binding to tissue factor, the plasma serine protease factor VIIa is essentially inert from the catalytic perspective and thus impervious to the abundant protease inhibitors in plasma.[289] Factor VII also competes with factor VIIa for tissue factor binding, thus serving as a negative regulator that buffers the overall reaction.[290,291] Factor VII–activating protease (FSAP) has also been shown to activate factor VII in the absence of tissue factor.[292–294] The physiologic function of FSAP still is unclear, but most recently has been suggested to be involved in inflammation (see the review listed in the References[295]). The extrinsic tenase complex (tissue factor–factor VIIa) activates low levels of the zymogens factor X and factor IX to their respective serine protease enzymes factor Xa (≈10 pM) and factor IXa (≈1 pM).[296,297] Factor X is the more efficient and abundant substrate.[298,299]

The extrinsic tenase complex is under tight supervision by TFPI, which can bind both the complex and the product factor Xa (see Fig. 125.13).[300,301] TFPI, present in low abundance in blood, is released from the vasculature by heparin.[302] If the initiating procoagulant stimulus is sufficient to overcome the level of this anticoagulant response, a threshold is exceeded and downstream complexes can be formed.

The limited amounts of factor Xa that escape inhibition by TFPI and antithrombin bind to available membrane sites and can activate tiny amounts of prothrombin to thrombin (see Fig. 125.13).[303] The time period in which factor Xa directly generates picomolar amounts of thrombin[304] is referred to as the *initiation phase* of blood coagulation (Fig. 125.13). During the initiation phase, circulating blood cells and procoagulant proteins are activated,[305] the procoagulant elements necessary for the full procoagulant response are generated, and a preliminary fibrin network is formed.[306] Although this process is inefficient, this initial thrombin is essential for the acceleration of the process by serving as the activator of platelets through cleavage of protease–activated receptors (PAR1 and PAR4)[307] and the activation of the procofactors factor V and factor VIII.[129] Thrombin also activates factor XI to factor XIa,[130] initiating the accessory pathway that enhances factor IX activation.[308]

In analyses of tissue factor–induced activation of the coagulation process in whole blood, the initial period of thrombin generation (based on levels of thrombin–antithrombin complexes) illustrates that most catalyst formation occurs before fibrin clot formation (see Fig. 125.13).[305] The small amount of thrombin that is generated during the initiation phase is from the extrinsic factor tenase and is able to activate platelets,[309] factor XIII,[310] factor V,[311] and factor VIII,[312] and release some fibrinopeptide A and fibrinopeptide B[263] from fibrinogen to form fibrin. Less than 2% of the final thrombin produced is required to achieve the activation of these catalysts produced in blood to form the initial clot. However, activation of the catalysts is essential to generate the bulk of thrombin (≈95%) that is formed during the propagation phase of the reaction. The aggregated platelets and fibrin resulting from thrombin formation are the principal components of the initial vascular plug formation. It has recently been shown that a fraction of red blood

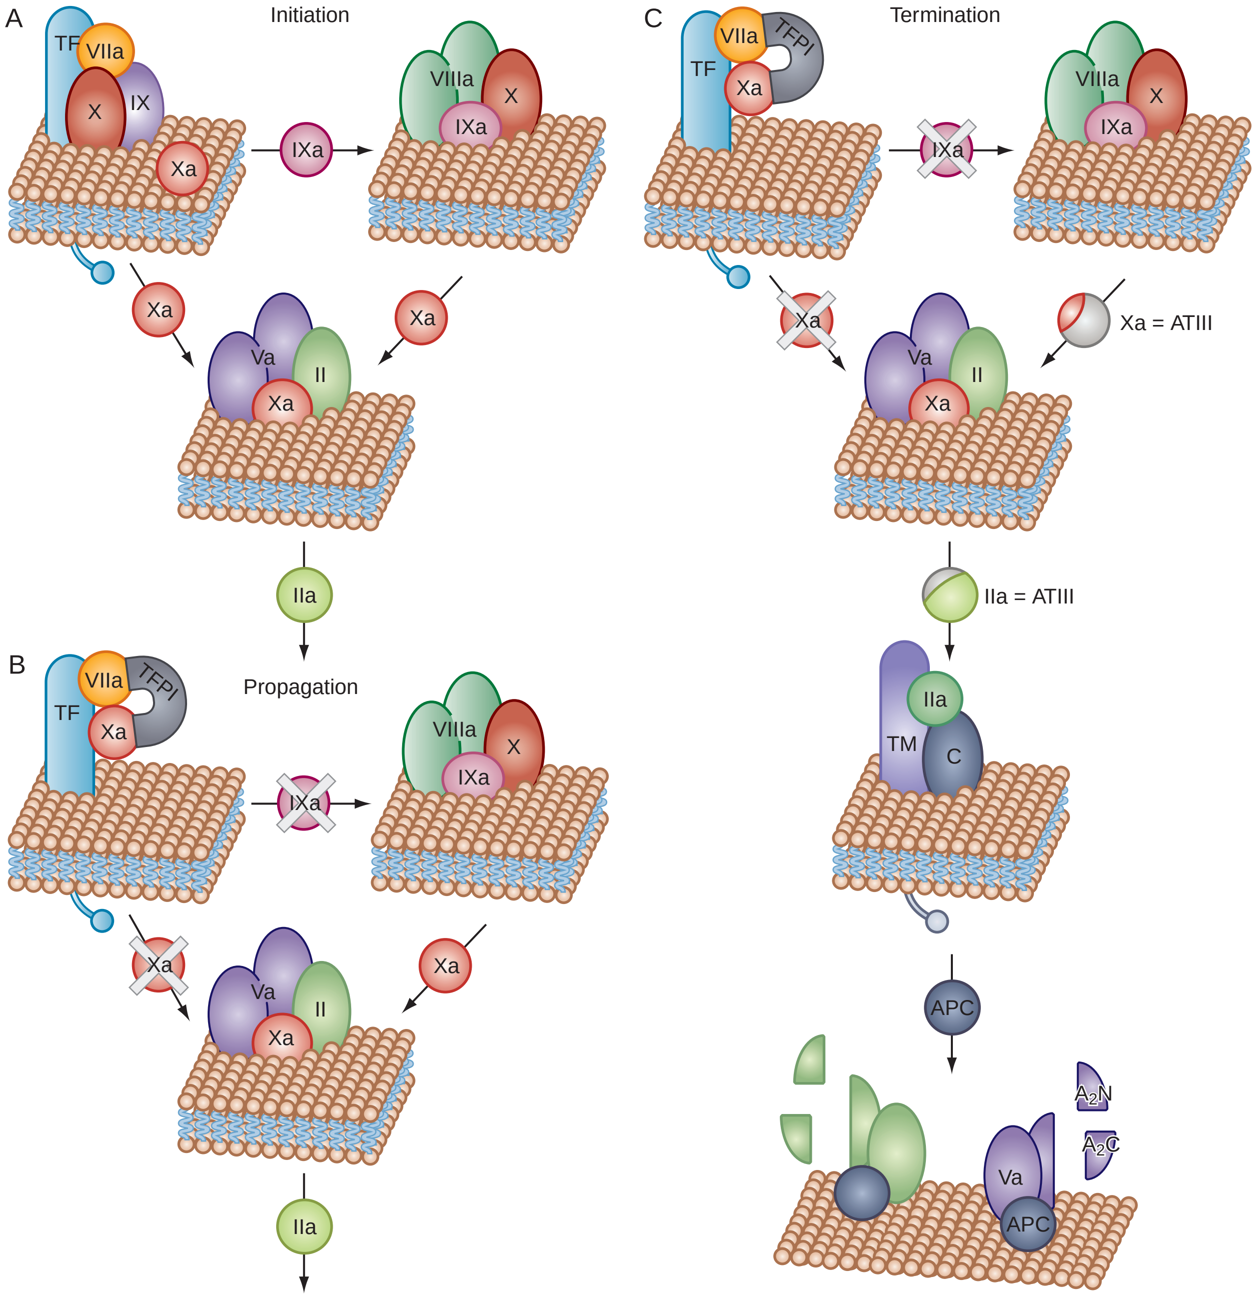

Figure 125.13 REGULATION OF THE DYNAMIC PROCOAGULANT RESPONSE. Initiation (A), propagation (B), and termination (C) of thrombin generation and the procoagulant response are illustrated. Four vitamin K–dependent complexes are shown: extrinsic tenase, intrinsic tenase, prothrombinase, and protein Case (C). The procoagulant response is regulated by the stoichiometric inhibitors antithrombin (AT) and TFPI. AT inhibits thrombin, factor Xa, and factor IXa that are free in solution. Tissue factor pathway inhibitor (TFPI) inhibits both factor Xa and the factor VIIa–TF–factor Xa complex. Activated protein C (APC) generated from the protein Case complex (thrombomodulin [TM]–thrombin [IIa]) inactivates factor Va and factor VIIIa by proteolysis of their heavy chains. Low levels of thrombin are required to initiate clot formation (initiation phase) and trigger the coagulation cascade response (propagation phase). The enzymes, cofactors, and inhibitors act together to generate a hemostatic response that can be divided into an initiation phase and a propagation and termination phase. During the initiation phase, factors X and IX are converted to their respective serine proteases factor Xa and factor IXa; low levels of thrombin are subsequently generated by factor Xa. This thrombin then can activate platelets and the procofactors factors V and VIII, which stimulate further thrombin generation during the propagation phase. Thrombin generation is attenuated by shutting down the initiation phase by means of the stoichiometric inhibitor of the extrinsic tenase complex, TFPI, followed by AT, which directly inhibits thrombin and factors Xa and IXa. *TF*, Tissue factor. *(From Mann KG. Coagulation Explosion. Burlington, VT: Vermont Business Graphics; 1997, with permission.)*

cells (≤1%) provide phosphatidyl serine–associated membrane receptors that can support the procoagulant complexes. These red blood cells are responsible for approximately 30% of all thrombin formation.[313]

After cofactor factor VIIIa is formed, it combines on activated platelets with the serine protease factor IXa that was generated by the tissue factor–factor VIIa complex to form the intrinsic tenase complex (see Fig. 125.13). This complex is the major activator of factor X; it is 50-fold more efficient than factor VIIa–tissue factor in catalyzing factor X activation.[299,314] The extrinsic tenase complex is under the control of TFPI.[315,316] In the absence of factor VIII (hemophilia A) or factor IX (hemophilia B), the intrinsic tenase complex cannot be assembled; thus no amplification of factor Xa generation occurs. This is the principal defect observed in hemophilia[317,318]:

initial production of factor Xa by the tissue factor–factor VIIa complex is inadequate to efficiently stem blood flow.

Factor Xa combines with factor Va on the activated platelet membrane surfaces at specific receptor sites to form the prothrombinase complex; the principal generator of thrombin (see Fig. 125.13).[319,320] This process serves as a major amplification loop of blood coagulation. The factor IXa and factor Xa constituent of prothrombinase and the intrinsic tenase complex are protected from inhibition by antithrombin and other plasma inhibitors when in the complexed form.

Propagation

When a sufficient stimulus is provided to overcome the antagonist–inhibitor threshold, the accumulating mass of activated platelets will support increasing intrinsic tenase and prothrombinase complex formation on their surfaces through specific platelet receptors, and the local inhibitor concentrations are overwhelmed (see Fig. 125.13). These platelet-bound catalysts execute the propagation phase of the reaction, during which massive amounts of thrombin are produced.[321] This phase of thrombin generation continues independent of the initially presented tissue factor if there is a continuous supply of blood to deliver new plasma procoagulant reactants, platelets, and fibrinogen to the site of perforation in the vascular endothelium.

Essential to the formation of the prothrombinase complex is the generation of factor Xa. Factor Xa is a unique regulatory enzyme in that it is formed through both the intrinsic tenase and the extrinsic tenase complexes. Under normal conditions, the concentration of factor Xa is the rate-limiting component of the prothrombinase complex. The other components of the complex, platelets (membrane surface–binding sites), and the cofactor (factor Va) are activated rapidly to produce a surplus that is ready for action.[319] The coagulation mechanism can become sensitive to factor V or platelets when confronted with congenital deficiencies, thrombocytopenia, platelet pathology, or pharmacologic interventions.[322,323]

The initial factor Xa is generated via the tissue factor–factor VIIa complex during the initiation phase. Additional factor Xa is

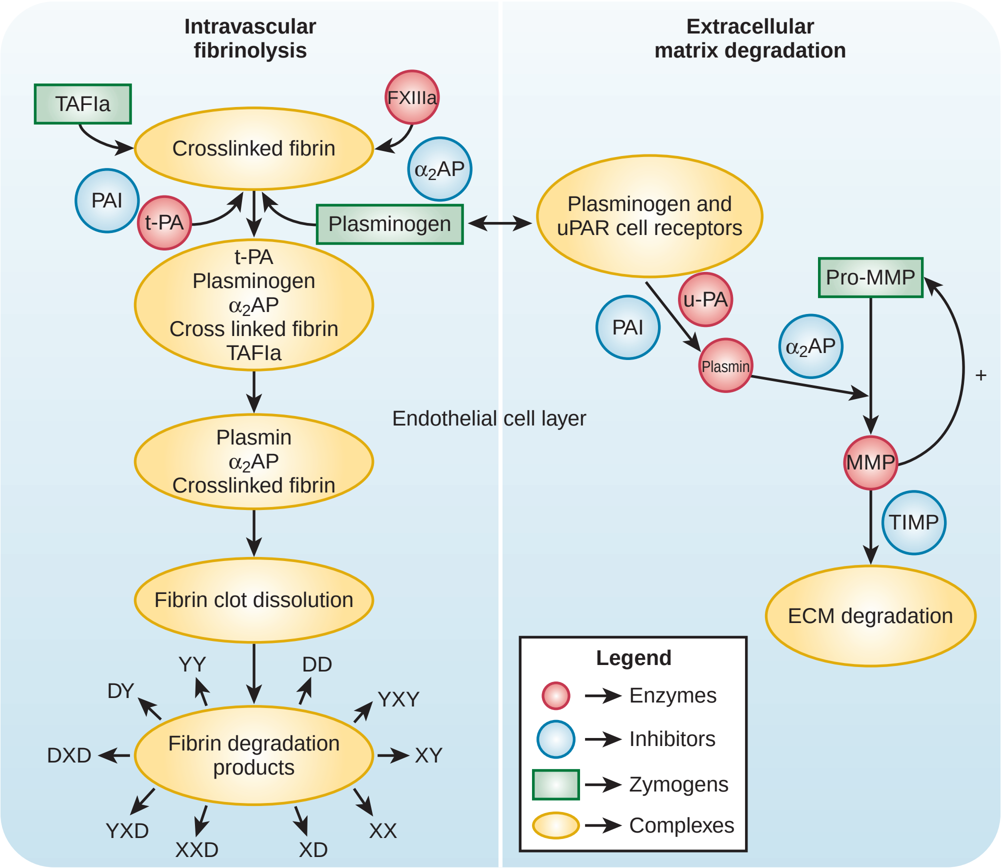

Figure 125.14 SCHEMATIC OF THE DYNAMIC INTERACTION BETWEEN THE PROTEINS AND INHIBITORS OF FIBRINOLYSIS. Cross-linked fibrin formation is integrated with fibrin clot dissolution and degradation of its products. Two pathways are shown, intravascular fibrinolysis and extracellular matrix, separated by an endothelial cell layer. The enzymes *(red circles)*, inhibitors *(blue circles)*, zymogens *(green boxes)*, and complexes *(large yellow ovals)* are illustrated in a simplified form to show this multi-component process. The key proteins of the fibrinolytic system *(left panel)* are plasminogen, the plasminogen activator t-PA, PAIs, α2-AP and TAFI, and the transglutaminase FXIIIa. t-PA and plasminogen both bind to the fibrin surface, cross-linked by FXIIIa, where t-PA is an effective catalyst of plasminogen conversion to plasmin. Initially, plasmin proteolysis of fibrin generates new COOH-terminus lysine residues, which function as higher affinity binding sites for plasminogen, setting up an amplifying loop of plasminogen activation. The formation of activated TAFI (TAFIa) results in the removal of the plasmin-generated COOH-terminus lysine residues, thus suppressing the rate of fibrin lysis. Opposing these events are antifibrinolytic mechanisms. Soluble and cross-linked α2-AP complexes with plasmin, rendering it inactive. PAI rapidly reacts with t-PA, thus reducing the concentration of the plasminogen activator. Fibrin degradation occurs by plasmin cleavage at the D-E-D domains of fibrin polymers to yield a variety of polymers as illustrated (for a definition of the D-E-D domain, see Fig. 125.11). Plasminogen can cross the endothelial cell layer and become converted to plasmin by u-PA *(right panel)*. Plasmin can convert latent MMPs (pro-MMPs) to their active form (MMPs). MMPs themselves can act in a positive-feedback mechanism to convert pro-MMPs to more MMPs, which ultimately degrade the extracellular matrix. Plasmin-mediated effects are inhibited by PAI and α2-AP. MMP-mediated effects are inhibited by TIMPs. *α2-AP*, α2-Antiplasmin; *ECM*, extracellular matrix; *FXIIIa*, activated factor XIII; *MMP*, matrix metalloproteinase; *PAI*, plasminogen activator inhibitor; *t-PA*, tissue plasminogen activator; *TAFI*, thrombin-activatable fibrinolysis inhibitor; *TIMP*, tissue inhibitors of metalloproteinases; *u-PA*, urokinase plasminogen activator.

then generated by the intrinsic tenase complex (factor IXa–factor VIIIa–membrane–Ca^{2+}). Initially, the concentration of the factor VIIa–tissue factor complex is higher than the concentration of the factor VIIIa–factor IXa complex, which requires activation and assembly. As time progresses, the contribution of the intrinsic tenase complex to factor Xa generation exceeds that of the extrinsic tenase.[324] The intrinsic tenase complex is kinetically more efficient and activates factor X at a 50- to 100-fold higher rate than the extrinsic tenase complex.[299,325,326] The burst of factor Xa that is generated overcomes the levels of factor Xa inhibitors, such as TFPI, and achieves maximal prothrombinase activity and propagation of the procoagulant response.[162,315] The bulk of thrombin (≈ 95%) is formed during the propagation phase after fibrin clot formation.[305,327] Without the intrinsic tenase complex being formed, as occurs in hemophilia A or B, factor Xa is not generated in levels sufficient to produce the propagation phase of thrombin generation.[317,328]

Because the presentation of a clot in a low tissue factor model depends on the generation of 10 to 30 nM thrombin,[305,327] at high tissue factor concentrations, tissue factor–factor VIIa generates factor Xa rapidly and masks the contribution of the factor VIIIa–factor IXa complex in clot end point assays. This is the case for the PT[266,267] in which the concentration of the initiator, thromboplastin (tissue factor and phospholipid), is chosen to produce a clot time of 11 to 15 seconds. This corresponds to a tissue factor concentration over 20 nM. In our whole-blood studies, a concentration of 5 pM tissue factor is used, which produces a clot time in the range of 5 minutes.[305,327] Therefore in hemophilia A, the PT does not reflect a change in clot time in this well-established hemorrhagic disease. The major defect occurs after clot time, during the propagation phase of thrombin generation, which is dramatically decreased.[317,321,329]

Termination

When blood flow has ceased because of the formation of a fibrin–platelet "dam," the overwhelming concentration of inhibitors present in blood, including TFPI and antithrombin, heparin cofactor II, α_2-macroglobulin, α_1-antitrypsin, and protein C inhibitor, can "catch up" and inhibit the various reactants as they dissociate from their respective complexes (see Fig. 125.13).[150,315,330–332]

In the intact vasculature surrounding the growing thrombus, procoagulant enzymes and cofactors escaping the wound site are rapidly quenched under normal circumstances by the stoichiometric and dynamic inhibitory systems of blood in cooperation with elements of the vascular endothelium. The free serine proteases (thrombin, factor IXa, and factor Xa) of the coagulation system in the plasma environment are rapidly inhibited by the surplus of antithrombin molecules. The reaction is accelerated by the interaction of antithrombin with heparan sulfate proteoglycans presented constitutively on the surface of vascular endothelial cells.[333]

Any thrombin escaping from the wound site may bind resident thrombomodulin molecules constitutively expressed by vascular endothelial cells. Thrombomodulin-bound thrombin is converted from a procoagulant enzyme to an anticoagulant enzyme.[334,335] The thrombin–thrombomodulin complex (protein Case) activates protein C, which in turn downregulates the intrinsic factor tenase and prothrombinase procoagulants by cleaving factor VIIIa and factor Va, respectively. The rates of APC inactivation of factors Va and VIIIa are enhanced by protein S. TAFI is also activated by protein Case and serves to delay clot lysis (see reviews listed in the References[53,336]). Cleavage of factor Va by APC and inhibition of thrombin generation also reduces thrombin–thrombomodulin–mediated TAFI activation.[337]

When operating properly, this system of blood leakage attenuation displays the appropriate level of procoagulant required to obstruct blood loss but is precluded from systemic activation of the coagulation system. The converse to hemostasis occurs when the damaging insult for the vasculature is internal to the vessel lumen.[338]

Elimination and Fibrinolysis

The hemostatic or pathologic thrombus is structurally composed of aggregated platelets and cross-linked fibrin. The steps in thrombin generation of a cross-linked fibrin clot are shown diagrammatically in Fig. 125.11. Other plasma proteins and blood cells are also trapped within the clot. Clot formation is integrated with clot dissolution by plasmin to maintain hemostatic balance. The plasminogen system has two roles: t-PA generates plasmin at the fibrin surface and governs fibrin homeostasis, and u-PA binds to a cellular u-PA receptor (u-PAR) and generates pericellular plasmin, which plays an important role in tissue remodeling and cellular migration (see Fig. 125.14).[339,340] The latter function is, to a great extent, mediated by plasmin activation of matrix metalloproteinases, which degrade ECM. t-PA and u-PA are secreted by vascular endothelial cells[341,342] and are regulated by cellular cytokines and components produced during the clotting cascade, including thrombin.

In the absence of fibrin, t-PA is a poor enzyme.[343–345] However, both t-PA and plasminogen bind to the fibrin surface with a resulting 100-fold enhancement in plasminogen activation. Thus t-PA activation of fibrinolysis is primarily initiated by and localized to fibrin.[343,345] The digestion of fibrin by plasmin[346] is seen in Fig. 125.14 and further described under the section Fibrinolysis Proteins.[274,346–349]

Fibrinolysis is regulated primarily by PAI-1,[350,351] PAI-2,[352] α_2-antiplasmin, and TAFI.[353] The antagonism between PAI-1 and the plasminogen activators u-PA and t-PA provides a threshold response of the fibrinolytic process in much the same way as the procoagulant–anticoagulant balance provides an activation threshold for the clotting process.[354–357] α_2-Antiplasmin is the primary inhibitor of plasmin.[358–360] Plasmin, when bound through its lysine binding sites to fibrin, reacts more slowly with α_2-antiplasmin than when free in solution because α_2-antiplasmin interacts with plasma plasmin by binding to the lysine binding sites.[358–362] In contrast, α_2-antiplasmin, bound covalently by factor XIIIa to the Aα chain of fibrin, blocks plasmin binding and appears to decrease plasminogen activation.[363] TAFIa functions in vitro as an antifibrinolytic factor by suppressing the positive-feedback pathway of fibrinolysis.[255,256,337]

The elimination phase begins the process of tissue repair by dissolving the fibrin–platelet clot generated in the earlier phases of hemostasis. The damaged vascular tissue not only requires plasmin to clear the fibrin clot, but also to initiate removal of damaged tissue to allow for cell migration into the injured area.[364,365] Plasmin activates a variety of matrix metalloproteinases that degrade subendothelial matrix components and extricate the damaged tissue.[365,366] These processes mark the beginnings of the final stages of the hemostatic response, repair, and regeneration.

The importance of the tight regulation of these processes is perhaps best illustrated by malfunctions of the hemostatic response. An inappropriate response can lead to one of two opposing but equally undesirable outcomes. Failure to form a sufficient hemostatic plug to arrest blood flow subsequent to vascular injury can result in pathologic hemorrhage. Excessive clot formation or failure to efficiently lyse a clot may result in thrombosis with consequent vascular obstruction. Under normal circumstances, the vascular endothelium together with the aforementioned positive- and negative-feedback loops within the procoagulant pathways prevent these negative outcomes by actively controlling the coagulation process until a triggering stimulus of sufficient magnitude threatens vascular integrity (Fig. 125.15). Initiation of the procoagulant response also initiates the fibrinolytic response simultaneously with repair and regeneration processes.

SUMMARY

This chapter describes the process of blood coagulation (extrinsic and intrinsic pathway) by dividing it into sections based on procoagulant, anticoagulant, and fibrinolytic enzymes, cofactors, and inhibitors in the overall process of fibrin formation and fibrin dissolution.

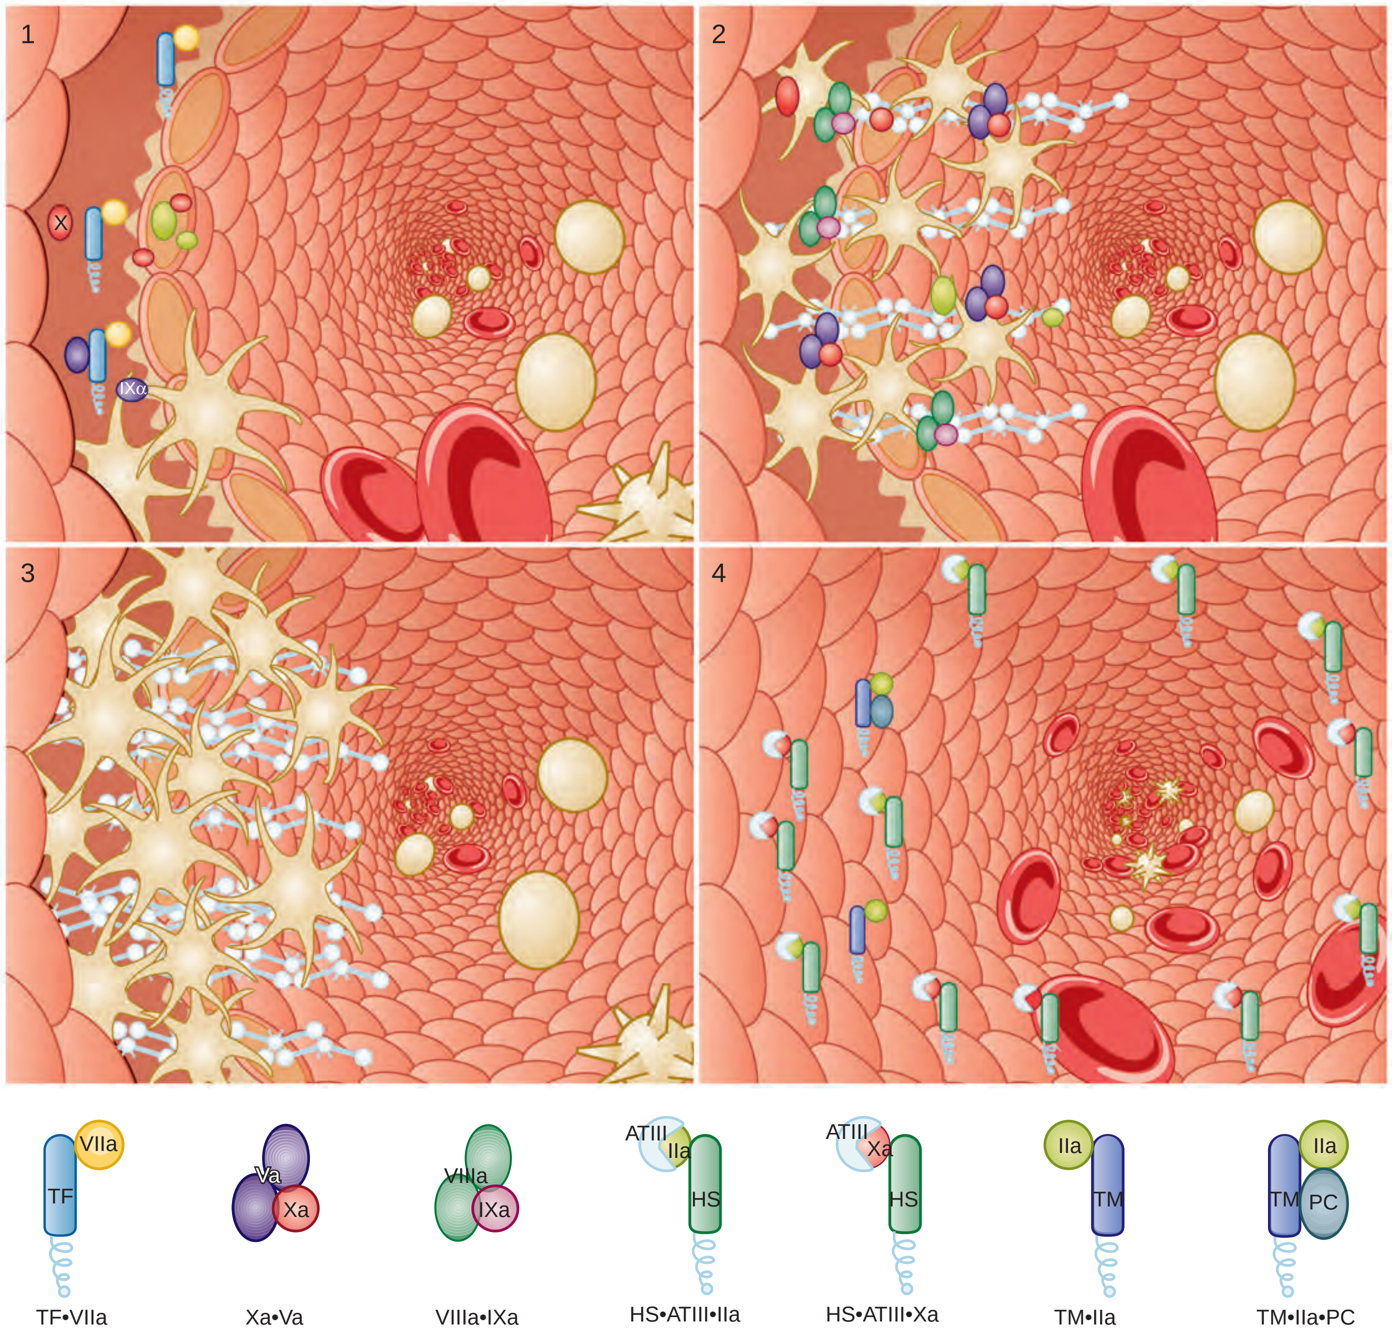

Figure 125.15 SCHEMATIC OF THE DYNAMIC EVENTS DURING TISSUE FACTOR–INITIATED BLOOD COAGULATION. A cross-section of a blood vessel showing the luminal space, endothelial cell layer, and extravascular region is presented at the site of perforation. The blood coagulation process in response is depicted in four stages. *Extrinsic tenase* complex, TF•VIIa; *prothrombinase* complex, Xa•Va; *intrinsic tenase*, VIIIa•IXa; antithrombin (AT)–endothelial cell heparan sulfate (HS) proteoglycan complex bound to thrombin or FXa, HS•AT•(IIa or Xa); protein C bound to thrombomodulin (TM)–thrombin, TM•IIa•PC. *Stage 1*. Perforation results in the delivery of blood, and with it circulating factor VIIa and platelets, to an extravascular space rich in membrane-bound tissue factor (TF). Platelets adhere to collagen and von Willebrand factor associated with the extravascular tissue, and TF binds factor VIIa, initiating the process of factor IX and factor X activation. Factor Xa activates small amounts of prothrombin to thrombin, which activates more platelets and converts factor V and factor VIII to factor Va and factor VIIIa. *Stage 2*. The reaction is propagated by platelet-bound intrinsic tenase and prothrombinase, with the former being the principal factor Xa generator. Initial clotting occurs and fibrin begins to fill in the void in cooperation with activated platelets. *Stage 3*. A barrier composed of activated platelets ladened with procoagulant complexes and enmeshed in fibrin scaffolding is formed. The reaction in the now-filled perforation is terminated by reagent consumption, attenuating further thrombin generation, but functional procoagulant enzyme complexes persist because they are protected from the dynamic inhibitory processes found on the intravascular face. *Stage 4*. View downstream of the perforation. Enzymes escaping from the plugged perforation are captured by antithrombin–heparan complexes, and the protein C (PC) system is activated by residual thrombin binding to endothelial cell TM, initiating the dynamic anticoagulant system. These intravascular processes work against occlusion of the vessel despite the continuous resupply of reactants across the intravascular face of the thrombus. *(From Orfeo T, Butenas S, Brummel-Ziedins KE, et al. The tissue factor requirement in blood coagulation. J Biol Chem. 2005;280:42887, with permission.)*

When all of the players are present, the overall process of blood coagulation and fibrinolysis is best described as a dynamic threshold-limited, complex, intertwined process that together promotes hemostasis.

ACKNOWLEDGMENTS

We the authors would like to thank Matthew Gissel in the preparation of this chapter. The authors were supported by the NIH-DOD TACTIC study 1-UM-1-HL120877-2, the Systems Biology program ARO-W911NF-10-1-0376, and by the United States Naval Health Research Center contract W911QY-15-C-0027.

CHAPTER 126

EVALUATION OF THE PATIENT WITH SUSPECTED BLEEDING DISORDERS

Catherine P. M. Hayward and Alice D. Ma

Bruising and bleeding are common reasons for a hematology referral.[1] Some consults are for management of an acute bleed in someone who may have a hemorrhagic disorder. Such bleeds may be spontaneous or occur after surgery or trauma, and the potential bleeding disorder may be inherited or acquired. With acute bleeding problems, the approach to patients must be rapid and directed at urgent restoration of hemostasis. Some referrals are for evaluation after an unexpected bleeding episode or the diagnosis of a bleeding disorder in a family member. Some of these referrals may be urgent because of upcoming procedures.

The assessment of such patients must be individualized, including a detailed history of the current and all past bleeding events, a detailed family history, and a thorough review of all medications, including nonprescription and supplemental agents. The assessment of bleeding or bruising can be challenging because individuals without bleeding problems often experience minor bleeding symptoms.[2] Furthermore, most individuals referred for assessment of bleeding or bruising will have experienced some bleeding symptoms that may or may not reflect an underlying bleeding disorder.[1] Because many individuals referred to a hematologist for evaluation will be diagnosed with a bleeding disorder, there is a high pretest probability for a bleeding disorder among such patients.[1] The next step is laboratory evaluation, guided by the pretest probability of finding an underlying bleeding disorder.[1] It is important to note that laboratory studies can yield false-positive findings,[1,3] and external pressures (e.g., insurance coverage) may limit the diagnostic testing available to the patient and physician. Finally, the hematologist must formulate a differential diagnosis and plan for bleeding symptom management (e.g., control of heavy menstrual bleeding [HMB]), including strategies to minimize future bleeding risks from exposure to surgery and other invasive procedures). Fig. 126.1 provides a general guide to the steps involved in clinical assessment.

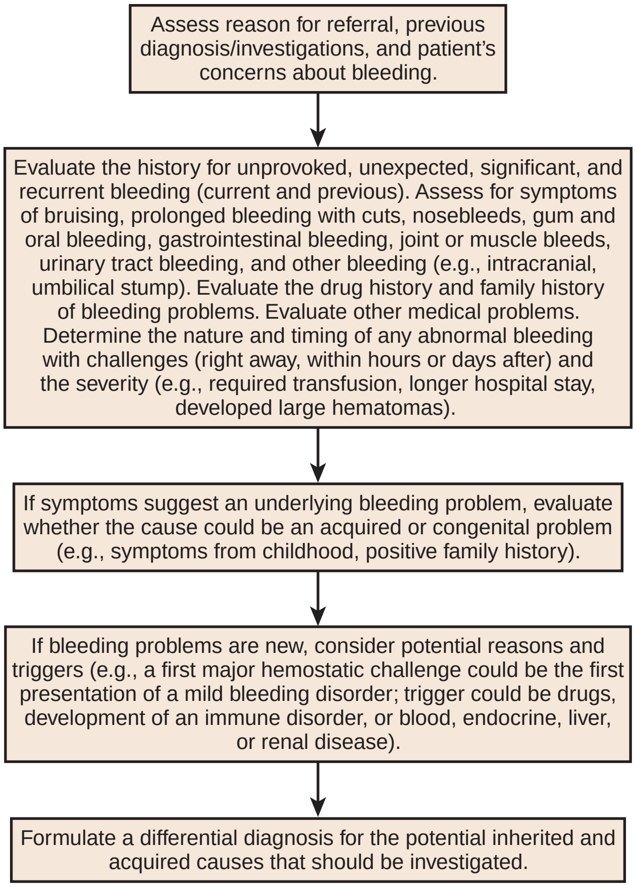
BLEEDING HISTORY EVALUATION

When evaluating a bleeding history, it is important to recognize that the presenting problems are influenced by the following factors:

1. The nature and severity of the defect, and the presence of single or multiple risk factors for bleeding
2. Whether the bleeding problem is congenital or acquired
3. Antecedent exposure to hemostatic challenges (e.g., surgery, dental extraction, menses, and childbirth) and the risk for bleeding with each of these challenges
4. The presence of other medical problems (e.g., renal, hepatic, or thyroid disease), including anemia
5. Variability in the bleeding symptoms experienced by individuals without bleeding disorders (e.g., nosebleeds, bruising) and by individuals with known bleeding disorders, even within families with the same defect
6. Local factors (e.g., sun-damage to the skin, vascular lesions, diverticular disease, or cancerous lesions in the gastrointestinal [GI] tract) and the possibility of nonaccidental trauma
7. Treatments that increase the risk for bleeding (e.g., antiplatelet agents, such as aspirin and nonsteroidal antiinflammatory drug [NSAID] used for pain control, anticoagulants)
8. Whether treatments were used to prevent or control bleeding
9. Whether treatments prescribed for other reasons may have reduced bleeding (e.g., reduced menstrual bleeding while on oral contraceptives to prevent pregnancy)

A detailed history of bleeding episodes, including assessment of the family history, is critical for an accurate assessment of whether a bleeding diathesis is present, as well as the nature of such a bleeding tendency. Questions should therefore be aimed at determining the likelihood of a bleeding disorder being present as well as the type of the putative bleeding diathesis (is this a disorder of primary or secondary hemostasis?) and its inheritance pattern. The history should include an orderly description of bleeding during infancy and childhood, including umbilical stump bleeding (characteristic of factor XIII deficiency [see Chapter 135]), bleeding with circumcision (characteristically seen in boys with severe hemophilia A or B [see Chapter 134]), bleeding with loss of deciduous teeth, and bleeding with childhood trauma and surgeries (see Chapters 148 and 155). Bleeding with dental procedures, including wisdom tooth removal, should be explored. Questions such as “Did you have to go back for stitches? Did you awaken with a pillow covered with blood? How many days of bleeding did you experience after your dental extractions?” are more specific than “Did you bleed with tooth removal?” Patients with milder bleeding disorders may only bleed with procedures involving mucosal surfaces, due to the high levels of fibrinolytic activity at these sites. Epistaxis may be a presenting symptom of von Willebrand disease (VWD) or hereditary hemorrhagic telangiectasia (HHT) and is especially notable if it does not stop with pressure and requires either cautery or a visit to the emergency department. Other bleeding episodes, whether spontaneous or provoked, should be elucidated. Bleeding into muscles and joints is characteristic of moderate or severe disorders of humoral clotting factors[4] and some fibrinolytic defects (e.g., Quebec platelet disorder[5]), whereas mucosal bleeding is typical of disorders of primary hemostasis.[6,7] Easy bruising is a complaint voiced by many persons without underlying bleeding disorders,[2] but certain historical features are worth noting. The new onset of bruising can herald a new thrombocytopenic disorder such as immune thrombocytopenia (ITP) (see Chapter 129) or acute leukemia (see Chapters 60, 63, 66, 67 and 68), or it can point to acquired hemophilia (see Chapter 134). Bruising which only occurs over the hands and forearms in older individuals suggests the presence of senile purpura. Some cases of bruising can be explained by fragile skin caused by sun exposure, cigarette smoking, or corticosteroid use. Other cases of bruising can be provoked by use of serotonin reuptake inhibitors or herbal supplements. Lastly, there are rare syndromic bruising disorders such as the Gardner-Diamond syndrome, mostly seen in young women with underlying psychiatric disorders, with a characteristic pattern and appearance to the bruises.[8]

Each individual surgical and major dental procedure undergone by the patient should be explored in depth.[9] The details of bleeding, including timing (immediate or delayed), the need for transfusion, comments by the surgeon concerning the characteristics of the bleeding (e.g., did it start on the day of the surgery/procedure or days later?), any known anatomic sources of bleeding, etc. can illuminate the bleeding diathesis. Immediate bleeding may be more characteristic of a disorder of primary hemostasis,[6] whereas delayed bleeding is seen more in patients with deficiencies in humoral clotting factors and fibrinolytic defects.[4,5] Bleeding in patients with an underlying



Assess reason for referral, previous diagnosis/investigations, and patient's concerns about bleeding.
Evaluate the history for unprovoked, unexpected, significant, and recurrent bleeding (current and previous). Assess for symptoms of bruising, prolonged bleeding with cuts, nosebleeds, gum and oral bleeding, gastrointestinal bleeding, joint or muscle bleeds, urinary tract bleeding, and other bleeding (e.g., intracranial, umbilical stump). Evaluate the drug history and family history of bleeding problems. Evaluate other medical problems. Determine the nature and timing of any abnormal bleeding with challenges (right away, within hours or days after) and the severity (e.g., required transfusion, longer hospital stay, developed large hematomas).
If symptoms suggest an underlying bleeding problem, evaluate whether the cause could be an acquired or congenital problem (e.g., symptoms from childhood, positive family history).
If bleeding problems are new, consider potential reasons and triggers (e.g., a first major hemostatic challenge could be the first presentation of a mild bleeding disorder; trigger could be drugs, development of an immune disorder, or blood, endocrine, liver, or renal disease).
Formulate a differential diagnosis for the potential inherited and acquired causes that should be investigated.

Figure 126.1 STEPS TO EVALUATE BLEEDING AND BRUISING PROBLEMS.

primary hemostatic defect is typically described as "diffuse oozing," without the readily identifiable bleeding source seen with a surgical mishap, such as a severed vessel. Patients with primary hemostatic defects often report that their bleeding occurred on the day of surgery,[6] rather than days later, which would suggest a coagulation factor deficiency or a fibrinolytic disorder. If a woman has bled with some procedures but not others, she should be asked if she was on estrogen-containing medications during the procedures in which she had good hemostasis, because estrogen can increase levels of von Willebrand factor (VWF), leading to normalization of hemostasis. Bleeding with some but not all procedures also suggests a mild rather than a severe disorder.[6]

Women should be carefully questioned about their menstrual history.[10,11] Duration and severity of flow[10,11] are more important than the presence or severity of cramping. Although HMB is medically defined as loss of more than 80 ml of blood per menstrual cycle,[11] few women are capable of determining this with any degree of precision. Pad or tampon use is imprecise as well because the number of sanitary products used may vary with the degree of fastidiousness of each patient. To that end, pictorial assessments of blood loss (depicting pads or tampons with varying degrees of saturation) have been devised, with scores given for numbers of products used and their saturation.[12] An underlying bleeding disorder is found in up to one-third of adolescents and adults who present with HMB.[10,13–16] Historical features correlated with a higher likelihood of an underlying bleeding disorder being found include "flooding" and "gushing" accidents, passage of clots larger than 1 cm, duration longer than 7 days, heavy flow greater than 3 days, and the development of iron deficiency.[6] While bleeding during pregnancy is less common in women with VWD, platelet function disorders, and most other bleeding disorders (exceptions include fibrinogen disorders, plasminogen activator inhibitor-1 [PAI-1] deficiency, and factor XIII deficiency), postpartum hemorrhage is more commonly seen compared with the general population.[6,7] Postpartum hemorrhage usually occurs 24 to 48 hours after delivery, and in women with bleeding problems, postpartum bleeding (lochia) can continue beyond the normal 6 weeks.[9]

A family history of bleeding should be carefully sought out, with consideration of whether consanguinity is culturally accepted by the family. The family history evaluation may require several visits to fully document, as familial memories are probed. A family history of bleeding with surgical procedures, bleeding requiring transfusions, and HMB leading to hysterectomy at a young age should be queried. However, a negative family history does not rule out a congenital bleeding disorder. Approximately one-third of all cases of hemophilia A arise from spontaneous mutations.[17] Many of the rare coagulation disorders, including deficiency of factors II, V, VII, and X (see Chapter 135), Glanzmann thrombasthenia (see Chapter 124)), and VWD type 2N (see Chapter 133), among others, are inherited in an autosomal recessive fashion,[18] and other family members may be entirely asymptomatic or bleeding problems may be limited to siblings. (See Case 1: Illustration of a Mild, Inherited Bleeding Problem.)

Certain medications and herbal and dietary supplements increase the risk of bleeding. The use of these agents may precipitate a hemorrhage in those with milder bleeding disorders. The use of aspirin and nonsteroidal antiinflammatory agents impairs primary hemostasis (see Chapter 128), and their use should be avoided prior to surgery or prior to evaluation of the hemostatic system. Their inclusion in over-the-counter products seems ubiquitous, and careful attention to cold and flu remedy use is warranted. In the Southeast United States, aspirin-containing remedies such as Goody powders or BC powders are not viewed as medications, and their use must be specifically queried.

Without treatment, severe bleeding disorders typically cause abnormal bleeding with all major hemostatic challenges.[19–21] In contrast, bleeding may not occur with every challenge in persons with milder defects.[6] Age influences the bleeding history by increasing the likelihood of exposures to hemostatic challenges and the development of sequelae such as arthropathy in patients with severe hemophilia[4] and Quebec platelet disorder.[5] A severe unexplained bleed with surgery may be considered suspicious of a bleeding problem. However, if the person reports that prior challenges did not result in bleeding, this narrows down the possibilities to a mild inherited bleeding disorder, an acquired bleeding disorder, an iatrogenic condition (e.g., bleeding while on anticoagulant therapy or a technical problem during surgery that caused bleeding), or a problem that is not related to a congenital or acquired bleeding disorder (e.g., a postpartum hemorrhage after a caesarean section from uterine atony or retained products of conception).

A bleeding disorder assessment needs to consider both familial and personal bleeding symptoms (see Case 2: Illustration of The Importance of Assessing Both Personal and Familial Bleeding Problems). However, a familial tendency toward bleeding may "pseudonormalize" bleeding symptoms and make recognition of abnormal bleeding patterns difficult. (See Case 3: Illustration of Delayed Recognition of Abnormal Bleeding.)

The timing of bleeding with challenges is evaluated to determine whether the bleeding problem reflects a common bleeding disorder, such as VWD, a platelet function disorder, an undefined mucocutaneous bleeding problem, or a rarer cause, such as a defect or

CASE 1: ILLUSTRATION OF A MILD, INHERITED BLEEDING PROBLEM

A 77-year-old man who is starting treatment for multiple myeloma was discovered to have a prolonged activated partial thromboplastin time (see Chapter 126). Review of his records indicated that the abnormality was present on a previous admission for spinal cord compression, which was treated with surgery. He required 4 units of packed red blood cells several days after this surgery because of delayed postoperative bleeding. There was no other bleeding history. He was found to have mild factor IX deficiency (see Chapter 134), unrelated to the myeloma, and his daughter proved to be a carrier of this defect.

CASE 2: ILLUSTRATION OF THE IMPORTANCE OF ASSESSING BOTH PERSONAL AND FAMILIAL BLEEDING PROBLEMS

A 24-year-old special forces paratrooper was evaluated for life-threatening bleeding. Following a routine practice jump, he felt a “pop” in his abdomen and developed progressive abdominal pain and generalized weakness. Upon evaluation, he had eventual syncope, a hemoglobin of 3 g/dL, and a CT scan showing a large abdominal wall hematoma. Arteriogram revealed extravasation of contrast material from a ruptured artery. Coil embolization was unsuccessful, and the patient became progressively hypotensive, hypothermic, and acidemic. Next of kin was contacted, and the patient’s father disclosed a history of hemophilia in the patient’s maternal uncle. The factor IX level was found to be 6%, and infusion of factor IX concentrate led to cessation of bleeding (see Chapter 134). Notably, the patient’s nickname during basic training was “Bruise.”

CASE 3: DELAYED RECOGNITION OF ABNORMAL BLEEDING

A 35-year-old woman presented with life-threatening hemorrhage following hysterectomy. She had a lifelong history of abnormal bleeding, including gum bleeding (“spat out a mouthful of blood” with brushing), abnormal bruising, and a personal and family history of heavy menses (during teenage years, mother and sister also had heavy menstrual bleeding, enough so that the mother would announce “time for new mattresses” every few years). This pattern of bleeding was felt to be “normal for the family.” The patient was eventually diagnosed with von Willebrand disease (see Chapter 133) and a qualitative platelet disorder (see Chapter 124).

CASE 4: ILLUSTRATION OF THE IMPORTANCE OF ASSESSING BLEEDING PROBLEMS OVER TIME

A 72-year-old man was referred for evaluation of a severe bleed after receiving a single dose of low-molecular-weight heparin for unconfirmed deep vein thrombosis. He had a history of a similar bleeding episode several years previously while on warfarin treatment for atrial fibrillation. There was no other bleeding history, and the patient subsequently developed a spontaneous iliopsoas bleed. He had undergone numerous surgeries earlier in life without any bleeding problems, and there was no family history of bleeding. The bleeding history suggested the possibility of an acquired bleeding problem, possibly acquired von Willebrand disease or an acquired factor deficiency. Diagnostic testing indicated that he had acquired factor XIII deficiency (see Chapter 135). This case illustrates the fact that there may be more than one risk factor for bleeding: in this case, several exposures to anticoagulants triggered bleeding in a patient with an acquired factor deficiency. On initial treatment of his iliopsoas bleed with factor XIII concentrate, there was partial neutralization of the infused factor followed by accelerated clearance, consistent with acquired factor XIII deficiency secondary to an autoantibody.

CASE 5: EVALUATION OF AN ISOLATED SYMPTOM—RECURRENT PREGNANCY LOSS WITH BLEEDING

A 32-year-old woman was referred for evaluation of a low fibrinogen level in the setting of acute placental abruption, resulting in a third pregnancy loss (this time in the third trimester). She had no prior bleeding history apart from having suffered three placental abruptions associated with severe bleeding that required transfusion. The family history was negative for bleeding problems. She had previously been investigated for thrombophilia but had not been tested for a bleeding disorder. The low fibrinogen level persisted over many months (levels of approximately 90 mg/dL), suggesting that the defect was inherited (see Chapter 135). She received fibrinogen concentrate for two subsequent pregnancies, which she carried to term and delivered without bleeding problems. This case illustrates the need to consider inherited disorders when the bleeding symptoms are unusual and severe, even if there is only one bleeding symptom. It also illustrates that prognosis is dependent on diagnosis and treatment.

deficiency in a coagulation factor or fibrinolytic protein (see Case 4: Illustration of the Importance of Assessing Bleeding Problems Over Time). Although patients will often know whether bleeding began on the day of a challenge[6] or if it started days later,[5] their recall of timing details is often better when procedures were done without general anesthesia (e.g., dental extractions, biopsies).

A newborn or child presenting with spontaneous intracranial hemorrhage or a large cephalohematoma should be investigated for severe underlying bleeding disorders, such as thrombocytopenia, hemophilia, factor XIII deficiency, other coagulation factor deficiencies, or a severe defect in platelets or VWF (see Chapter 148).[19,20,22,23] Trauma-related subdural or intracranial hemorrhage can also be a manifestation of a severe bleeding disorder.[22] In adults, ischemic strokes are more frequent than hemorrhagic strokes (see Chapter 144), although hemorrhagic strokes appear to predominate in persons with some types of bleeding disorders (e.g., Quebec platelet disorder[5]), and they can also reflect complications of antithrombotic drug treatment.

Excessive or prolonged bleeding after childbirth or pregnancy loss can be problematic for some women with bleeding problems.[6,10–12,24] In addition, severe fibrinogen disorders, PAI-1 deficiency, and factor XIII deficiency compromise carrying a pregnancy to term and need to be excluded if the patient has unexplained pregnancy losses that are associated with hemorrhagic placental abruption[19,25,26] (see Case 5: Evaluation of an Isolated Symptom—Recurrent Pregnancy Loss With Bleeding).

BLEEDING SCORE

Objective frameworks for the evaluation of bleeding symptoms have been developed to codify clinical impressions into a numeric score.[7,9,10,27] These bleeding assessment tools (BATs) were initially developed as research tools to quantify bleeding symptoms and severities. Several BATs and their subsequent versions have been refined. They have been studied and validated in specific populations, including those being evaluated for VWD, platelet disorders, symptoms of HMB, and other bleeding syptoms.[6,7,10,27,28]

Several other tools have been developed with refinements of the original “Vicenza bleeding score” with similar formats: in a grid format, specific bleeding symptoms (e.g., epistaxis, dental hemorrhage) are scored in severity from trivial to severe, and then summed to a final bleeding score. Unfortunately, despite these refinements, the shared weakness of these tools is poor sensitivity (as low as 40%), which has not been greatly improved.[29] Whether these tools are appropriate for use in the clinical setting is still debated, but because of their high negative predictive value, they are probably best for identifying patients who do not require further testing. In addition, the bleeding scores may be useful in predicting future bleeding: in a large, prospective study of VWD, a higher bleeding score is the strongest predictor of bleeding, even over other laboratory and clinical assessments.[30] Whether the bleeding score’s predictive power holds true in other mild bleeding disorders is not yet known, although some studies have not shown the scores to be predictive of future bleeding.[27] Finally, in response to the variability of bleeding scores utilized in clinical studies that make comparing these studies challenging, the International Society on Thrombosis and Haemostasis (ISTH) has proposed a new consensus BAT with the goal of expanding the understanding of bleeding rates and phenotypes more precisely in congenital bleeding disorders.[9] Despite the ease of use and the good negative predictive value of various BATs, the judgement of an experienced clinician remains supreme. BATs have also been used to estimate bleeding risks as likelihood or odds ratios (relative to unaffected relatives or the general population) for experiencing different kinds of bleeding symptoms (e.g., bleeding with surgery, menses longer than 7 days, joint bleeds) and also risks for needing certain types of treatments, such as blood transfusion.[5,6]

THE PHYSICAL EXAMINATION

A careful physical examination may provide useful clues to the etiology of the patient's bleeding (Table 126.1). Examining the skin may reveal petechiae, indicating thrombocytopenia, or the characteristic ecchymoses, scarring, and lax skin seen with senile purpura. Patients with scurvy have characteristic perifollicular hemorrhages and "corkscrew" hairs. Telangiectasias around the lips or on the fingertips may signal the presence of HHT. Some patients with vascular Ehlers-Danlos syndrome exhibit characteristic "cigarette paper" skin, which is thin, crepey, and translucent.[31] Bruises should be examined for their number, pattern, and age—if they are all the same color and lividity, they may have all occurred simultaneously. It is important to determine whether the pattern of distribution is indicative of self-infliction, as can be seen sometimes in some patients with Munchausen syndrome. Oculocutaneous albinism is associated with several platelet disorders, including the Hermansky-Pudlak syndrome and the Chédiak-Higashi syndrome (see Chapter 124).[18] Splenomegaly can be associated with thrombocytopenia and may indicate underlying cirrhosis. Other stigmata of liver disease, such as spider angiomata, gynecomastia, asterixis, and jaundice, also suggest that the patient may have an associated liver coagulopathy. Joint hypermobility and skin hyperelasticity may be found in hypermobile Ehlers-Danlos syndrome, although not all patients with this disorder manifest the skin findings.[31] A harsh systolic murmur may indicate severe aortic stenosis, which can cause an acquired type 2 VWD, with associated GI bleeding from arteriovenous malformations (see Chapter 133).[32] An enlarged tongue, carpal tunnel syndrome, and periorbital purpura may point to amyloidosis (see Chapter 93), which can be associated with an acquired deficiency of factor X and many other clotting proteins, including factor V, VWF, α_2-antiplasmin, and PAI-1.[33–36] See Case 6 for an illustration of physical examination leading to clues to the cause of worsening bleeding.

CASE 6: THE PHYSICAL EXAMINATION ILLUMINATED THE CAUSE OF WORSENING BLEEDING SYMPTOMS

A 58-year-old man with type 2A von Willebrand disease (see Chapter 133) was evaluated for worsening gastrointestinal (GI) bleeding. He had a history of multiple GI bleeds attributed to arteriovenous malformations. Despite thrice weekly infusions of von Willebrand concentrate, his transfusion requirements were increasing from 2 units every 3–4 months to every 7–10 days. Evaluation revealed a new harsh systolic murmur. Echocardiography showed large mitral and aortic vegetations, and blood cultures grew *Staphylococcus epidermidis*, likely from his indwelling catheter. After valve replacement, his transfusion requirements markedly decreased, perhaps as the result of improvement in shearing of high molecular weight von Willebrand factor (VWF) multimers.

EPIDEMIOLOGY AND GENETICS

An understanding of the epidemiology of bleeding problems requires distinction between symptoms that rarely represent a pathologic condition and do not require investigation or therapy (e.g., isolated "easy bruising," brief nosebleeds) and those that are more suspicious, require treatment, and/or are highly predictive of a bleeding problem (Table 126.2).[1–3] Some individuals have multiple risk factors for bleeding (e.g., low VWF levels, exposure to drugs that inhibit platelet function after a surgical procedure associated with a high risk for bleeding).[3] Although some symptoms, such as nosebleeds, easy bruising, and HMB, are quite prevalent in the general population (10% or more report these symptoms),[2] these problems are more frequent and more severe in individuals with bleeding disorders.[5–7,12] In addition, cohort studies have shown that females with platelet disorders have more mucocutaneous bleeding symptoms than affected males.[6] HMB requiring treatment is common among women, and

TABLE 126.1 Physical Exam Clues to Bleeding Manifestations

Corkscrew hairs, perifollicular hemorrhages (typical of scurvy)
Oral blood blisters, particularly if the patient has thrombocytopenia
Ecchymoses, hematomas, and skin pigmentation changes because of recurrent bleeds
Ecchymoses limited to sun-exposed areas of the skin
Signs of active bleeding from a site of trauma or an incision, including excessive blood loss into drains
Sequelae of previous bleeds in individuals known or suspected to have a severe bleeding disorder, such as muscle wasting and arthropathy, neurologic abnormalities from prior intracranial, or compartment syndrome bleeds
Pallor arising from anemia: the palms are usually notably pale when the hemoglobin is less than 10 g/dL
Signs of an underlying hematologic disorder, such as lymphadenopathy and/or splenomegaly
Signs of acute or chronic liver disease, such as jaundice, hepatomegaly, spider nevi, palmar erythema, or Dupuytren contractures
Signs of an endocrine disorder, such as hypothyroidism or Cushing syndrome
Vascular lesions such as telangiectasia on the face, lips, tongue, buccal mucosa, or fingers which can suggest hereditary hemorrhagic telangiectasia
Joint hypermobility and skin laxity suggesting a collagen disorder
Signs suggestive of a syndromic bleeding disorder (albinism, hearing impairment, absent radii)

TABLE 126.2 Differential Diagnosis of Bleeding Problems

Major Categories	Comments
No bleeding disorder	Symptoms do not reflect a bleeding disorder and have another explanation (e.g., a surgical bleed not caused by a bleeding disorder).
Possible bleeding disorder	The laboratory findings are nondiagnostic, and the bleeding history is considered equivocal (e.g., unexplained serious bleed with one surgical procedure; unexplained heavy menstrual bleeding without other bleeding problems).
Definite bleeding disorder, undefined or indeterminate type (commonly referred to as bleeding of unknown cause)	The bleeding history is consistent with a bleeding disorder; however, the laboratory findings are nondiagnostic. Commonly the bleeding history resembles mild to moderate defects in platelet function or von Willebrand factor. The diagnosis should only be made once an adequate evaluation for common bleeding disorders (e.g., for von Willebrand disease, platelet aggregation defects, and platelet dense granule deficiency) is completed. If testing is not complete, the classification should indicate the types of conditions excluded or not excluded (e.g., mild mucocutaneous bleeding problem, von Willebrand disease excluded, mild mucocutaneous bleeding problem, platelet dense granule deficiency not yet excluded).
Definite bleeding disorder with a defined cause	The symptoms and laboratory findings are considered diagnostic of a bleeding disorder. Tables 126.3 and 126.4 summarize many of the potential inherited and acquired causes.

TABLE 126.3 Differential Diagnosis of Congenital Bleeding Disorders

Disorder	Comments
Fibrinogen deficiency or dysfunction	Deficiencies can be mild-moderate hypofibrinogenemia or severe afibrinogenemia. Fibrinogen function is abnormal in dysfibrinogenemias, which can present with bleeding, thrombosis, or both. Functional fibrinogen levels are reduced much more than immunofibrinogen levels in dysfibrinogenemias, whereas fibrinogen function and immunofibrinogen levels are similarly reduced in hypofibrinogenemia.
X-linked coagulation factor deficiencies—hemophilia	Presentation is influenced by the degree of deficiency. Factor VIII deficiency is more common than factor IX deficiency. If factor VIII is low, von Willebrand disease (especially type 2N) should be excluded as the cause.
Rarer, coagulation factor deficiencies	Deficiencies can affect factors XI, V, II, VII, or X, and the presentation is dependent on the severity of the deficiency. Hereditary deficiencies of multiple coagulation factors are rare (e.g., of factors V and VIII, or multiple vitamin K–dependent coagulation factors for congenital defects impairing γ-carboxylation) and can easily be excluded by measuring multiple factors.
Fibrinolytic defects	Causes include disorders caused by loss of function, such as α_2-antiplasmin or PAI-1 deficiency, and by gain-of-function defects, such as Quebec platelet disorder (overexpression of urokinase plasminogen activator in megakaryocytes).
von Willebrand disease	Causes include quantitative (partial type 1 to severe type 3) and qualitative defects (loss of function in type 2M and 2A, gain of function in type 2B and platelet type). Type 1 von Willebrand disease can be confused with low von Willebrand factor levels (e.g., because of blood group O) and its diagnosis needs to consider the bleeding history. Type 1C is a quantitative disorder due to abnormal clearance of VWF.
Platelet disorders	These conditions can affect platelet number, function, or both. The most common type of platelet function disorder includes disorders that impair aggregation responses and/or cause dense granule deficiency. Disorders of platelet function are commonly subclassified by the nature of the defect, such as the following: 1. Defects of membrane receptors for adhesive proteins (e.g., Glanzmann thrombasthenia and Bernard-Soulier syndrome) or agonists (e.g., $P2Y_{12}$ deficiency) 2. Defects of signaling or secretion (the largest subcategory), which include disorders caused by transcription factor mutations 3. Cytoskeletal defects (e.g., MYH9-related disorders) 4. Storage pool disorders (e.g., gray platelet syndrome, dense granule deficiency, αγ-storage pool deficiency, Quebec platelet disorder) 5. Defects of procoagulant function (e.g., Scott syndrome)
Vascular disorders	Congenital vascular malformation, including hereditary hemorrhagic telangiectasia, Ehlers-Danlos syndrome.

PAI-1, Plasminogen activator inhibitor 1.

it can sometimes be life-threatening in those with severe bleeding disorders. With moderate or severe disorders, there is less uncertainty about the disease prevalence than there is for milder disorders (e.g., type 1 VWD), where there is ongoing debate about the diagnostic criteria that define a pathologic abnormality (see Chapter 133). There is less information on the prevalence of disorders that require complex tests for diagnosis and have many potential causes (e.g., platelet function disorders). Bleeding of unknown cause (BUC) (i.e., definite bleeding problems despite normal or nondiagnostic test findings) has emerged as a common cause of mucocutaneous and postsurgical bleeding.[37]

The process of referral for bleeding makes it likely that the person has had some bleeding symptoms that may or may not reflect an underlying congenital (Table 126.3) or acquired (Table 126.4) bleeding problem.[1] Because of this referral bias, the prevalence of bleeding disorders in tertiary referral clinics is much higher than in the general population. The prevalence of inherited bleeding disorders in the general population is quite low (from 0.00023% to more than 1% for VWD, with much lower estimates based on studies of bleeding disorder clinic cases compared with those derived from population screening studies that used higher cutoffs to define quantitative deficiencies; 0.005% to 0.01% for hemophilia; and much lower for other coagulation factor deficiencies).[38] Consequently, unselected screening is not recommended. Founder effects in populations and cultural acceptance of consanguinity can alter the prevalence of both common and rare inherited bleeding disorders.

A person with a first-degree relative with an autosomal dominant bleeding problem or with a sibling with a recessively inherited disorder has a higher pretest probability of an inherited bleeding disorder. When assessing the relative of someone with a positive family history of a bleeding problem, it is important to realize that the person may have the same condition, with or without additional defects, or a different bleeding problem. Furthermore, it is common for affected family members to show some variability in the severity of their bleeding symptoms. Index cases typically have more severe bleeding symptoms (illustrated in reference[6]). Accordingly, laboratory investigations are often used to assess family members at high risk, even in the absence of a remarkable personal bleeding history. Patients may appear to have syndromic findings, but it is important to determine whether the separate findings on history and physical examination are coinherited and thus represent the syndrome—or are independently inherited and thus nonsyndromic. (See Case 7: Symptoms Seemingly Linked, But Not.)

CASE 7: SYMPTOMS SEEMINGLY LINKED, BUT NOT

An 18-year-old woman from Puerto Rico presented for evaluation of potential Hermansky-Pudlak syndrome (see Chapter 123), due to a lifelong history of abnormal mucocutaneous and postprocedural bleeding as well as oculocutaneous albinism. On further questioning, there was a family history of both albinism and abnormal bleeding, but these two features were not linked, (i.e., some family members with albinism did not bleed, and others who bled did not have albinism). Genetic testing was negative for Hermansky-Pudlak syndrome, and the patient was subsequently given the diagnosis of a qualitative platelet disorder, based on platelet function testing.

TABLE 126.4 Differential Diagnosis of Acquired Bleeding Problems

Disorder	Comments
Drug induced	Aspirin, NSAIDs, other platelet function inhibitors (e.g., $P2Y_{12}$ and $\alpha_{IIb}\beta_3$ inhibitors), anticoagulants, fibrinolytic drugs, and antidepressants are common causes.
Acquired factor deficiencies	The causes can be immune (e.g., acquired factor VIII deficiency, acquired factor V deficiency) or nonimmune. Reductions in multiple factors can result from vitamin K deficiency, treatment with vitamin K antagonists, liver disease, hemodilution, and rarely snakebites. Severe acquired hypofibrinogenemia is commonly caused by a postpartum coagulopathy or severe liver disease but can also reflect hyperfibrinolysis. Prothrombin deficiency occurs with some lupus anticoagulants. Amyloidosis can cause an acquired factor X deficiency, which may be associated with reductions in other coagulation factors synthesized in the liver if the liver is involved.
Disseminated intravascular coagulation	The manifestations can include thrombocytopenia, consumption of coagulation factors, including fibrinogen, and impairment of hemostatic mechanisms from the fibrin/fibrinogen degradation products. Causes are wide ranging and include postpartum consumptive states, severe head injury, prostate and other cancers, and snakebites.
Acquired von Willebrand disease	The cause can be immune (often in association with an IgG paraprotein) or nonimmune (e.g., increased proteolysis of von Willebrand factor with stenotic aortic valvular disease).
Immune thrombocytopenia	Bleeding is usually influenced by the severity of the thrombocytopenia. Some autoantibodies interfere with platelet membrane receptor function, causing bleeding disproportionate to the thrombocytopenia.
Non–drug-induced, acquired platelet function disorders	The cause can be immune (see earlier) or nonimmune, typically from bone marrow disorders, although they can be secondary to Cushing syndrome or hypothyroidism.
Liver disease	Liver disease can cause thrombocytopenia, deficiencies of coagulation factors, hypofibrinogenemia and dysfibrinogenemia, and increased fibrinolysis. In mild liver disease, factor VII and sometimes factors XI and XII are low. Fibrinogen is often increased in early liver disease, and if low, the finding suggests severe liver disease.
Renal disease	Anemia is an important predictor of uremic bleeding. Uremic bleeding is typically associated with severe renal impairment.
Hypothyroidism	Hypothyroidism can cause an acquired von Willebrand disease and acquired defects in platelet function.
Cushing syndrome	This syndrome should be suspected when there are symptoms and findings suggestive of Cushing syndrome or treatment with systemic glucocorticoids.
Surgical bleeding	This is often a diagnosis of exclusion, although the procedural notes sometimes document that a technical problem was encountered that led to abnormal bleeding.
Vitamin K deficiency	Newborns are at risk, as are individuals with malabsorption and/or receiving broad-spectrum antibiotics that reduce vitamin K production by reducing gut bacteria. Older adults are also at greater risk for developing vitamin K deficiency because of reduced stores from poorer intake of vitamin K. If the patient does not respond to parenteral vitamin K, other causes should be considered.
Vitamin C deficiency (scurvy)	This diagnosis should be considered when there is lethargy with skin and gum bleeding (perifollicular hemorrhages, gum bleeding with swelling). The condition is rare in high-income countries. The cause is usually a very poor diet or malabsorption. Patients with end-stage renal disease who are nonadherent to vitamin repletion are at risk because vitamin C is removed with hemodialysis.

IgG, Immunoglobulin G; *NSAID*, nonsteroidal antiinflammatory drug.

LABORATORY MANIFESTATIONS

The general investigations that are appropriate for most assessments of bleeding problems include[1] a complete blood count with differential and peripheral smear,[2] a ferritin level to assess for iron deficiency,[3] a blood group and antibody screen, particularly for individuals with prior pregnancies or transfusions and upcoming surgery or major dental procedures, and[4] tests of renal function (creatinine) if antifibrinolytic therapy will be considered (because the dosage is dependent on renal function) and/or an MYH9-related disorder is suspected (see box on The Laboratory Manifestations of Bleeding Disorders).[1] The bleeding time test is no longer recommended because of its technical limitations and poor sensitivity to common bleeding disorders (see Chapter 127).[1] Electrolyte levels merit monitoring when repeated doses of desmopressin therapy are given and/or if the fluid balance is difficult to assess. Tests of liver function are warranted if the person has risks for transfusion-acquired, chronic liver disease. Tests for liver and thyroid disease (particularly hypothyroidism) can be helpful if the history suggests an acquired bleeding problem of unknown etiology.[1] Screening for Cushing syndrome (24-hour urine test for free cortisol) should be restricted to patients with acquired bleeding problems that suggest this possibility (e.g., bleeding associated with

THE LABORATORY MANIFESTATIONS OF BLEEDING DISORDERS

The laboratory manifestations of bleeding disorders can include abnormalities from the following:
1. The underlying hemostatic defect.
2. Bleeding complications (e.g., anemia, iron deficiency, coagulopathy secondary to hemodilution after resuscitation for a massive bleed, development of red cell antibodies after transfusion).
3. False-positive abnormalities (e.g., prolonged aPTT caused by incidental mild factor XII deficiency, which is found in approximately 1 of 200 patients (see Chapter 135), or a lupus anticoagulant (see Chapter 139), which can be a transient finding in approximately 5% of hospitalized patients).
4. Extremes of normal variation (e.g., slightly reduced von Willebrand factor levels in an individual who is blood group O, absent secondary aggregation with epinephrine in adjusted platelet rich–plasma aggregation studies).

obesity, the development of type 2 diabetes, hypertension, striae, and/or changes in physical appearance).[1]

The investigations for a bleeding problem typically also include screening tests (prothrombin time [PT], [aPTT], thrombin clotting time, and fibrinogen level), which are inexpensive tests, that detect acquired coagulopathies much more commonly than they detect inherited bleeding disorders because of differences in prevalence (see Chapter 126).[1] These investigations are useful as a baseline for individuals at risk for developing a dilutional coagulopathy from bleeding and as initial investigations of a possible inherited or acquired coagulation disorder. Abnormalities, if detected, require further evaluation to determine if the cause is a fibrinogen disorder or a deficiency of one or more coagulation factors.[1] Screening tests for VWD are warranted for individuals with a personal or familial history of mucocutaneous bleeding.[1] Platelet function disorders should be evaluated by aggregation tests and tests for dense granule deficiency, if available, because these tests are useful for assessing common bleeding disorders.[1,39] More detailed analyses for individuals with personal and family histories of bleeding disorders might include factor VIII measured by chromogenic assay.[1] Approximately 40% of individuals with mild hemophilia A have a discrepancy between the factor VIII activity measured by the one stage and chromogenic methods.[40] In some cases, the aPTT may be normal, the one stage factor VIII level may be normal, but the chromogenic factor VIII level can be low (see Case 8: Not All Cases of Hemophilia A Can Be Diagnosed with One Stage Factor VIII Assays). Chapter 127 provides more detail on the specific diagnostic tests that are appropriate for a laboratory workup of bleeding problems.

PROGNOSIS

The prognosis for bleeding problems depends on the severity and nature of the hemostatic defect, exacerbating factors, and whether these problems can be readily corrected (e.g., vitamin K to correct deficiency, discontinuing aspirin) or if they require hemostatic therapies, such as factor concentrates and/or drugs (e.g., desmopressin, tranexamic acid, or aminocaproic acid). Life expectancy is generally normal, even with the most severe bleeding disorders (e.g., severe hemophilia). The prognosis for some rare disorders significantly improves after puberty (e.g., factor IX Leyden). A few show progressive worsening over time (e.g., development of aplasia from congenital amegakaryocytic thrombocytopenia,[41] transformation of thrombocytopenia from an inherited RUNX1 mutation into myelodysplasia or acute myeloid leukemia[6]). Other disorders (e.g., acquired hemophilia) may go into complete remission after immunosuppressive treatment with risk for later relapses.[42]

CASE 8: NOT ALL CASES OF HEMOPHILIA A CAN BE DIAGNOSED WITH ONE STAGE FACTOR VIII ASSAYS

A 57-year-old woman presented for evaluation of bleeding following a face-lift. For several weeks after this procedure, she required extraction of facial hematomas. Her bleeding history was otherwise notable for absence of bleeding with laparoscopic hysterectomy or C-section together with a history of gum bleeding and bleeding with dental procedures. She had normal menses and no history of postpartum hemorrhage. She was on estrogen replacement therapy. Family history was notable for “factor VIII deficiency” in her father and a paternal uncle. Her father died of bleeding following a Whipple procedure without factor VIII repletion. Her sister had significant heavy menstrual bleeding, bleeding with multiple procedures, and postpartum hemorrhage. Her PT and aPTT were normal. Platelet function analyzer (PFA-100) testing showed normal closure times. One stage factor VIII activity was normal at 55%. Chromogenic factor VIII activity was low at 18%. Genetic analysis showed an *F8* c.5954G>A (p.Arg1985Gln), a pathogenic variant known to occur in the A3 region of the F8 gene, associated with mild hemophilia A and discrepant factor VIII assays.

Mild platelet function disorders, mild type 1 VWD, and many common undefined conditions that cause mucocutaneous bleeding usually respond well to prophylactic desmopressin and antifibrinolytic therapy, which is given to prevent bleeding with major surgical and dental procedures or bleeding with childbirth.[37,43,44] Nonetheless, it is important to have a specific diagnosis to manage situations in which desmopressin therapy alone is insufficient to control bleeding.

Women with bleeding disorders have a similar prognosis to men, although they often have a greater burden of symptoms because of HMB and childbirth-related bleeding, and they often report more mucocutaneous bleeding.[7,39] Their outcomes with pregnancy and childbirth appear to be more similar to individuals without bleeding disorders when they receive treatment to control bleeding with delivery.[6,24] However, some disorders have sufficiently good outcomes with childbirth that treatment for uncomplicated childbirth is not required (e.g., for Quebec platelet disorder[5]). Childbirth plans for women with bleeding disorders require consideration of the options for pain management and avoidance of procedures, such as spinal or epidural anesthesia, to limit bleeding risks unless the defect can be readily corrected.[45]

THERAPY

An individual’s bleeding history is an important consideration whenever formulating therapeutic plans to control and minimize bleeding risks. Some symptoms do not warrant therapy (e.g., bruising), whereas treatment is important for controlling HMB and for preventing and limiting challenge-related bleeding (e.g., from major or minor surgery and dental and endoscopic procedures, and traumas). For severe disorders, prophylactic treatment is warranted to prevent spontaneous bleeding and to limit challenge-related bleeding, which can be severe. The focus of therapy for some acquired conditions (e.g., acquired hemophilia) is immunosuppressive therapy to achieve a remission while managing any acute bleeding that warrants therapy.[42] For individuals with mild bleeding disorders, who have undergone multiple prior surgical procedures without bleeding, it may be appropriate to have treatment available (e.g., desmopressin on “standby”) that is to be administered if and when abnormal bleeding occurs, provided that the procedural-related risks of bleeding are small and readily managed (e.g., biopsy under local anesthetic) while waiting for the medication to have an effect.

For women with bleeding disorders, there are general treatments that can be considered for symptomatic management regardless of the type of bleeding disorder. For example, options for HMB management include oral contraceptives, antifibrinolytic drugs, and hormone-releasing intrauterine devices.[11] When HMB limits lifestyle and further pregnancies are not desired, surgical options (endometrial ablation, hysterectomy) may be preferred options, particularly when menopause is not imminent.

General management of bleeding often includes supportive care, correction and prevention of anemia (e.g., iron replacement for iron deficiency), and immunization against viruses that may be acquired by blood transfusion (e.g., hepatitis A and B) (see Case 9: Illustration of Changes in Bleeding Outcomes With Treatment). If the patient is immobilized or is undergoing a procedure with significant risks for thrombosis, there should be plans for thromboprophylaxis if the defect can be corrected during this treatment (e.g., by factor replacement therapy for hemophilia or VWD, fibrinolytic inhibitor therapy for Quebec platelet disorder) or for alternative thromboprophylaxis if this is not possible (e.g., use of pneumatic compression devices without anticoagulant drugs if the treatment will provide only brief hemostatic correction [e.g., desmopressin, platelet transfusions]).[46] Other measures to limit bleeding risks from bleeding disorders, with surgery, include the avoidance of intramuscular injections, spinal and epidural anesthesia, and NSAIDs for pain management. In older individuals with bleeding disorders and symptomatic atherosclerotic disease (e.g., angina), aspirin therapy may be appropriate, with increased vigilance for signs and symptoms of significant bleeding.[46]

CASE 9: ILLUSTRATION OF CHANGES IN BLEEDING OUTCOMES WITH TREATMENT

A 38-year-old woman was evaluated for a bleeding disorder. Her family physician had already excluded the possibility of von Willebrand disease. The patient had a long-standing history of massive bruises, often without recollection of trauma, prolonged nosebleeds requiring medical attention since early childhood, prolonged bleeding from minor cuts, and severe bleeding requiring blood transfusions with many surgical procedures. She had a history of recurrent iron deficiency anemia, HMB requiring medical therapies, and immediate postpartum bleeding. Her father had a history of bleeding problems, but the cause of the bleeding problem in the family was unknown. The history suggested an inherited disorder, possibly a platelet function disorder or a form of von Willebrand disease. The testing indicated that she had a platelet secretion defect with multiple aggregation abnormalities, with no evidence of von Willebrand disease. She underwent additional surgical procedures, using desmopressin treatment to reduce her bleeding risks, with no abnormal bleeding. Her HMB was controlled with tranexamic treatment. She self-administered desmopressin treatment to control nosebleeds, with good effect. This case illustrates that treatment affects bleeding outcomes and the importance of evaluating for common defects in hemostasis.

For more information on therapies for specific disorders, see the chapters on hemophilia (Chapter 134), rare coagulation factor deficiencies (Chapter 135), VWD (Chapter 133), and platelet disorders (Chapters 124 and 128).

SUMMARY

The evaluation of a patient with a suspected bleeding disorder is complex and potentially confusing. A thorough history (and perhaps in the future, a BAT score) and physical examination will help the clinician determine the pretest probability of an underlying bleeding diathesis and thus guide the laboratory investigation. Despite these tests, some patients with a convincing personal and family history of abnormal bleeding may have laboratory evaluations that remain unrevealing. Therapy should be guided toward replacing the deficient hemostatic element, either as needed or prophylactically, depending on the individual circumstances.

CHAPTER 127

LABORATORY EVALUATION OF HEMOSTATIC AND THROMBOTIC DISORDERS

Menaka Pai and Karen A. Moffat

This chapter provides a practical approach to the laboratory evaluation of hemostatic and thrombotic disorders. Any assessment of hemostatic or thrombotic disorders must start with a thorough history and physical examination. These can provide clues to guide subsequent laboratory testing, diagnosis, and management.

Physiologic hemostasis is a complex interplay of cellular or plasma elements: the adhesion of platelets to damaged endothelium, the aggregation of platelets to form a temporary plug, the successive activation of coagulation factors to form a stabilizing fibrin clot, clot retraction to repair endothelial damage, and finally clot breakdown through fibrinolysis (Fig. 127.1). Commonly available laboratory tests focus on the individual components of hemostasis by testing coagulation proteins, platelets, and fibrinolytic proteins; this chapter is organized into similar components to provide a structured laboratory approach to the patient with a hemostatic or thrombotic problem. Yet the clinician must be mindful that in the body, the components of hemostasis work together to form a product that is more than the sum of its parts.

LABORATORY EVALUATION OF COAGULATION PROTEINS

The Physiology Underlying Laboratory Evaluation of Coagulation Proteins

For over half a century, the process of fibrin clot formation has been conceptualized as a “coagulation cascade.” This is based on the waterfall hypothesis of Davie, Ratnoff, and MacFarlane, who almost simultaneously reported a sequence of proteolytic reactions starting with factor XII (Hageman factor) activation by surface contact and ending with thrombin’s proteolysis of fibrinogen to form fibrin.[1,2] However, upon its introduction, this hypothesis of successive necessary proteolytic reactions already appeared to be too simplistic. Nearly a decade earlier, Ratnoff had identified that deficiencies of factor XII were not associated with bleeding; others soon established that deficiency of factor XII’s cofactors (prekallikrein and high-molecular-weight kininogen) also did not result in a bleeding phenotype. In 1977, Osterud and Rappaport recognized that the factor VIIa/tissue factor complex can activate factor IX to factor IXa.[3] Broze later recognized that this complex cannot directly activate factor X, because of the presence of tissue factor pathway inhibitor (TFPI); factor IX activation is a prerequisite in vivo (see Chapter 124). Though deficiency of factor XII and its antecedents is not associated with bleeding, factor XI deficiency is (see Chapter 134). In 1991, Gailani and Broze explained this by proposing that factor XI can be activated independently of factor XII, as formed thrombin cycles back to activate factor XI and thus amplifies its own formation.[4] Factor XII, long considered to have no role in coagulation in vivo, has been found to play a role in thrombus formation and angiogenesis.[5] Our understanding of hemostasis has advanced still further in recent years, as blood coagulation research is increasingly performed under flow conditions with cellular elements in vitro and in animal models.

The physiologic “coagulation cascade” now appears to be an intricate system with built-in shortcuts and feedback loops. It is triggered by factor VIIa in complex with tissue factor, and results in the activation of zymogens that become serine proteases.[4] This system functions in concert with platelet activation and fibrinolysis (Fig. 127.2). However, clinical laboratory testing of coagulation proteins is not based on this current understanding—it follows the original Ratnoff-Davie-Macfarlane surface-activated coagulation cascade hypothesis.[1,2] These tests attempt to mimic in vivo processes by carrying them out in vitro, and thus do not capture the true complexity of physiologic hemostasis. They are still useful in diagnosing coagulation protein deficiencies and important bleeding disorders. However, they can be misleading, as they can also detect abnormalities of questionable clinical significance. The clinician must therefore understand the distinction between the complexity of physiologic hemostasis and the simplistic picture presented by laboratory tests.

As we proceed in reviewing tests for coagulation proteins, we can place them into three technical categories:

1. **Immunologic tests**, which include enzyme-linked immunosorbent assays (ELISA), immunoelectrophoresis, and immunoturbidometric (latex immuno-agglutination) tests. These tests are quantitative and detect specific proteins with polyclonal or monoclonal antibodies. Their sensitivity and specificity depend on the antibody used (polyclonal versus monoclonal) and the presence of interfering substances (e.g., rheumatoid factor, human anti-mouse antibody (HAMA), and other autoantibodies).
2. **Chromogenic or amidolytic assays**, which measure the activity of the serine proteases of the coagulation system as they react with synthetic peptides. The reaction (and thus the activity of serine protease) can be measured as the synthetic peptide releases a colored dye. Chromogenic assays are affected by the specificity of the peptide substrate. A disadvantage of these assays is that their narrow measure of an enzyme’s activity may not correlate with its biologic activity in vivo or its activity in clot-based assays.
3. **Clot-based or coagulation assays** are functional and compare the clotting potential of a patient’s plasma with control plasma with a known clotting potential. These tests are more difficult and time-consuming to perform than the others, and are susceptible to interference from other factors, such as anticoagulant effect and hemolysis-icteric-lipemic (HIL) interferences. However, they most closely approximate in vivo hemostasis.

SCREENING FOR COAGULATION PROTEIN DEFECTS: ACTIVATED PARTIAL THROMBOPLASTIN TIME, PROTHROMBIN TIME, AND THROMBIN CLOTTING TIME

The three assays most often used to screen for coagulation protein defects are: (1) the activated partial thromboplastin time (APTT), induced in vitro by surface-activation of prekallikrein, high-molecular-weight kininogen, and factor XII; (2) the prothrombin time (PT), induced in vitro by the addition of excess tissue factor; and (3) the thrombin clotting time (TCT), a test of fibrinogen integrity and thrombin inhibition. The PT, APTT, and TCT are clot-based assays that measure the rate of clot formation and are based on the

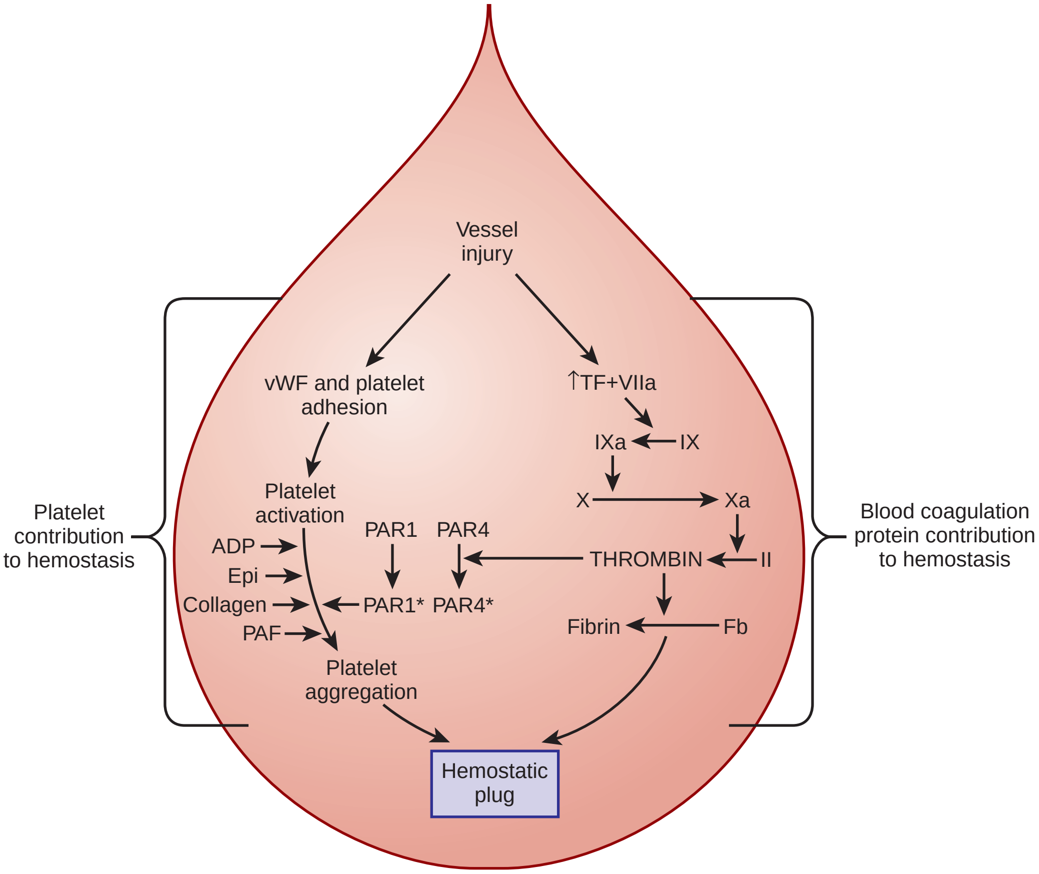

Figure 127.1 SCHEMATIC DIAGRAM OF HEMOSTASIS. Two equally important arms of activity contribute to physiologic hemostasis. The platelet contribution to hemostasis is as follows. When a vessel is injured, exposing collagen, platelets adhere to the injury site via vWF and, in high-shear areas, glycoprotein VI (not shown in figure). Upon adherence, the platelets are activated and release their granule contents. Released ADP and other granule contents recruit more platelets to the injury site. Simultaneously, subendothelial cell tissue factor exposed at the site of injury binds activated factor VII (VIIa) and activates factor IX to activated factor IX (IXa) and, sequentially, factor X to activated factor X (Xa), and prothrombin (II) to thrombin. Exposed collagen also promotes factor XII autoactivation and generation of additional thrombin in the milieu of activating platelets (not shown in figure). Thrombin stimulates more platelets, enhancing the platelet plug. Thrombin also proteolyzes fibrinogen to form fibrin monomer, which then polymerizes into a fibrin clot. These events occur on or about the activated platelet surface. *ADP*, Adenosine diphosphate; *Epi*, epinephrine; *Fb*, fibrinogen; *PAF*, platelet-activating factor; *PAR*, protease-activated receptor, *TF*, tissue factor; *vWF*, von Willebrand factor.

waterfall hypothesis of coagulation. They trigger a sequence of proteolytic reactions in the intrinsic, extrinsic, and common pathways (Fig. 127.3). The reactions culminate in the proteolysis of fibrinogen to form a fibrin clot, which causes soluble proteins to precipitate in the patient's plasma sample. These soluble proteins can be detected by either increased electric impedance or decreased optical clarity, depending on the instrumentation used to measure the result.

Any defect in one of the coagulation proteins along the pathway to clot formation will give an abnormal result (i.e., a delayed time to clot formation) (see Fig. 127.3). For example, factor XI deficiency will lead to a prolonged APTT. Furthermore, because clot formation depends on a series of reactions, any substance (e.g., inhibitory antibodies, anticoagulants) that interferes with the assay *downstream* from a specific coagulation protein will lead to an abnormal result. For example, profound fibrinogen deficiency will lead to a prolonged APTT and PT, even when the levels and function of all the upstream coagulation proteins are normal.

In the APTT assay, activation of the blood coagulation system occurs when factor XII and its cofactors encounter a negatively charged surface such as kaolin, celite, silica, or ellagic acid (hence the intrinsic pathway's alias as the "contact pathway"). This causes the protein to change shape, allowing its autoactivation and subsequent initiation of the cascade of proteolytic reactions seen in the coagulation system. The APTT measures many proteins that are critical to physiologic hemostasis, including factor VIII and factor IX. However, it also measures proteins like factor XII, prekallikrein, and high-molecular-weight kininogen that are not necessary for physiologic hemostasis. To perform the APTT assay, equal parts of a negatively charged surface and phospholipid mixture are incubated with patient plasma for a predetermined time. Calcium chloride is then added to recalcify the citrated plasma, and the time to clot formation is measured. The APTT assay measures all the proteins of the intrinsic system (prekallikrein, high-molecular-weight kininogen, factor XII, factor XI, factor IX, and factor VIII) and the proteins of the common pathway (factors X, V, prothrombin [factor II], and fibrinogen). These proteins have different threshold levels to which they must fall before the APTT shows an abnormality. For example, most commercial APTT reagents detect a decrease in factor VIII when the protein level decreases to 35% to 45% of normal (i.e., 0.35 to 0.45 U/mL). Alternatively, factor XII and high-molecular-weight kininogen levels must fall to 10% to 15% of normal before the APTT becomes significantly abnormal, however small decreases in these factors may cause slight prolongation. The sensitivity of the screening tests for detection of specific abnormalities varies with the factor being tested, the commercial reagent used in the assay, and the equipment platform for measurement. Each clinical laboratory should determine the level of decrease for each coagulation factor that produces an abnormal APTT with their current equipment and reagents.

In the PT assay, addition of excess tissue factor creates a nonphysiologic change in the normal stoichiometric relationship of

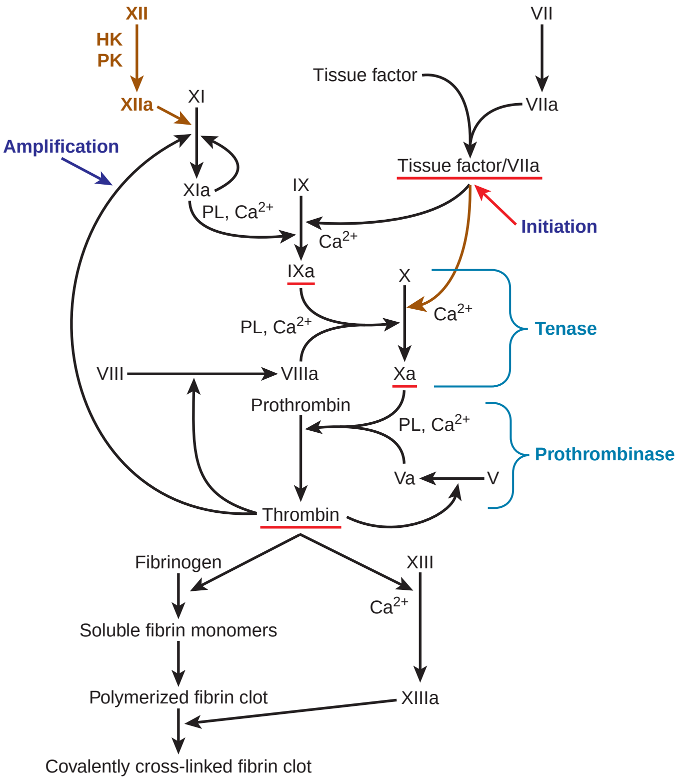

Figure 127.2 SCHEMATIC DIAGRAM OF PHYSIOLOGIC HEMOSTASIS. Formation of the tissue factor–activated factor VII complex (TF/VIIa) results in factor IX activation to activated factor IX (IXa). TF/VIIa does *not* normally activate factor X directly *(brown line)*. Activated factor IX activates factor X to activated factor X (Xa) in the presence of activated factor VIII (VIIIa), which is formed from prior thrombin activation of factor VIII (tenase). Xa in the presence of activated factor V (Va) activates prothrombin to thrombin (IIa) (prothrombinase). Thrombin proteolyzes fibrinogen to form a fibrin clot. If more thrombin is needed, thrombin can activate factor XI to activated factor XI (XIa), which then activates more factor IX to factor IXa, which makes more activated factor X and thrombin. If more thrombin-induced clot formation is needed, thrombin also activates thrombin-activatable fibrinolysis inhibitor, which inhibits fibrinolysis (pathway not shown). Factor XI also can be activated by activated factor XII, which is formed secondarily by the constitutive activation of prekallikrein in the presence of high-molecular-weight kininogen by contact activation in collagen-exposed injured vessels. These latter mechanisms are *not* constitutive for physiologic hemostasis. However, in non-physiological states, such as sepsis, clot formation in the intravascular compartment, or cardiopulmonary bypass, activated factor XII can activate factor XI to initiate hemostasis with thrombin formation. This latter mechanism is the basis of the activated partial thromboplastin time, a major screening test for hemostatic disorders. *HK*, High-molecular-weight kininogen; *PK*, prekallikrein; *PL*, phospholipid; *TF*, tissue factor; *Va*, activated factor V. *(Modified from Schmaier AH, Miller J. Coagulation and fibrinolysis. In: McPherson RA, Pincus MR, eds. Henry's Clinical Diagnosis and Management by Laboratory Methods. 22nd ed. Philadelphia: Elsevier; 2011:785.)*

coagulation factors, allowing factor VIIa to overcome the inhibitory effect of TFPI; the factor VIIa/tissue factor complex then activates factor X to factor Xa (this bypasses the usual physiologic requirement for this process to occur through factor IX activation). To perform the PT assay, one part patient plasma and two parts tissue thromboplastin (human or rabbit tissue-derived or recombinant human tissue factor) are added to phospholipid and calcium. The time required to clot formation is measured. The PT assay measures the extrinsic pathway of coagulation, which consists of factor VII and the proteins of the common pathway (factors X, V, II, and fibrinogen). Like the APTT, the PT becomes abnormal at different threshold levels for different factors, depending on the commercial reagent and the equipment platform. For example, factor VII levels must generally fall below 35% to 40% before the PT becomes abnormal.

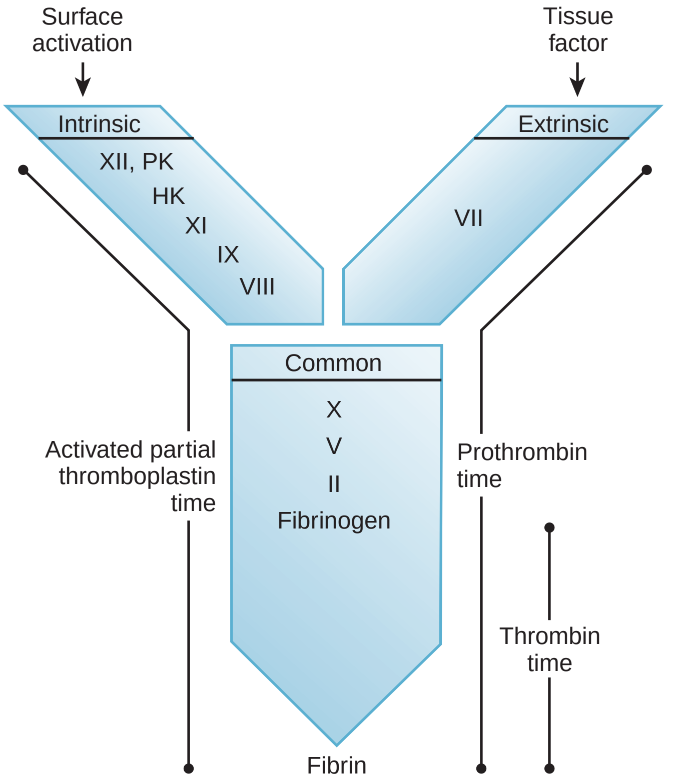

Figure 127.3 ORGANIZATION OF THE COAGULATION SYSTEM BASED ON CURRENT SCREENING ASSAYS. The intrinsic coagulation pathway consists of the protein factors XII, XI, IX, and VIII and prekallikrein and high-molecular-weight kininogen. The extrinsic coagulation pathway consists of tissue factor and factor VII. The common pathway of the coagulation system consists of factors X, V, II, and fibrinogen (I). The activated partial thromboplastin time requires the presence of every protein except tissue factor and factor VII. The prothrombin time requires factors VII, X, V, and II, and fibrinogen. The thrombin clotting time only tests the integrity of fibrinogen. *(Modified from Schmaier AH. Approach to the bleeding patient. In: Schmaier AH, Petruzzelli LM, eds. Hematology for the Medical Student. Philadelphia: Lippincott Williams and Wilkins; 2003:79.)*

The PT can also be used to monitor warfarin therapy if the test reporting is modified so it can be interpreted universally. Because of the plethora of commercially available PT reagents and coagulation instruments, it is impossible to know the normal range for the PT from any given laboratory. The international normalized ratio (INR) was thus developed to standardize the reporting of the PT and to create a universal benchmark for monitoring warfarin therapy. $\text{INR} = (\text{patient PT (sec)}/\text{mean normal laboratory PT (sec)})^{\text{ISI}}$, where the international sensitivity index (ISI) for a given thromboplastin reagent is a measure of its responsiveness to reductions in the levels of the vitamin K-dependent coagulation factors, factors II, VII, IX, and X. The ISI (provided by each reagent's manufacturer, but ideally locally validated) is based on the degree of variation of the thromboplastin reagent from the World Health Organization (WHO) reference thromboplastin. This reference has an arbitrarily assigned value of 1.0. INR derivation can be performed by developing a calibration line for any given thromboplastin, using orthogonal regression or linear regression, and incorporating the PT determined with the WHO standard.[6] Determination of the ISI requires samples from a minimum of 20 healthy donors and 60 patients on stable warfarin therapy with INR values ranging from 1.5 to 5.0.[7] The higher the ISI, the less sensitive the thromboplastin. In practice, changes in the INR are considered interchangeable with changes in the PT. However, the INR is correctly used only to characterize the degree of PT prolongation in samples from patients taking vitamin K antagonists such as warfarin.

In the TCT assay, exogenous thrombin is added to examine the integrity of its major substrate, fibrinogen. To perform this assay, purified thrombin is added to plasma, and the time to clot formation is measured. The TCT is thus a direct measure of the conversion of fibrinogen to fibrin (see Fig. 127.3). When performing this assay, it is essential to use the minimal amount of α-thrombin (3000 U/mg specific activity) that will reproducibly "clot" fibrinogen, usually 2 to 6 U/mL, aiming for a clotting time (CT) of approximately 20 seconds with pooled normal plasma to achieve maximal sensitivity and render the test clinically useful. This assay is distinguishable from the clottable fibrinogen assay (Clauss assay) by the amount of thrombin used. The clottable fibrinogen assay uses far more thrombin (100 U/mL) and determines the amount of functional fibrinogen in patient plasma compared with known levels of functional fibrinogen in calibration plasma.[8] A prolonged TCT, as indicated by values outside the 95% confidence interval for the time to clot of a large population of normal donor samples, suggests reduced fibrinogen levels (usually <100 mg/dL), abnormal fibrinogen function, or the presence of an inhibitor of the exogenous thrombin (e.g., heparin or a direct thrombin inhibitor). The TCT can also be prolonged if there is interference with fibrin polymerization, which can be caused by elevated levels of fibrinogen degradation products or the presence of a paraprotein. Some drugs, such as valproic acid, also prolong the TCT.[9]

EVALUATION OF SPECIFIC COAGULATION PROTEIN DEFECTS

When the APTT, PT, or TCT suggest a coagulation protein defect, the plasma concentration of the coagulation factors should be quantified. Factor assays determine the nature and degree of severity of coagulation protein defects and can also be used to monitor factor replacement therapy. Coagulation protein defects can take three forms: a true protein deficiency; an abnormal protein that cannot participate in its physiologic function(s); or an inhibitor that targets the active site of the protein or enhances its clearance. Inherited protein deficiencies and abnormalities can be caused by deletions, insertions, and missense/nonsense mutations in individual genes. Inhibitors are generally immunoglobulins, although abnormally produced endogenous heparin, fibronectin, or cryoglobulins can also serve as acquired inhibitors to coagulation proteins.

If a coagulation protein defect is suspected, clinical laboratory testing can be done with immunologic, chromogenic, or clot-based assays. Clot-based assays for coagulation proteins are functional: they will be abnormal with both true deficiencies and dysfunctional proteins. These take the form of one-stage assays that use the APTT (for factor XII, prekallikrein, high-molecular-weight kininogen, factors XI, IX, and VIII) or the PT (for factors VII, X, V, and II) as the platform. Specific factor–deficient plasma is the key to clot-based factor assays as it provides the required specificity for each assay. These assays are based on the principle that when plasma (either from a reference standard or from a patient) containing the factor is added to plasma completely deficient in that factor, it can "correct" (i.e., shorten) the prolonged CT. For example, a factor VIII assay requires APTT reagent and calcium chloride, WHO reference calibration plasma, factor VIII–deficient plasma (which has < 1 U/dL of factor VIII and normal levels of all other factors), and patient plasma. Several different dilutions of the reference plasma are set up, creating a range of known concentrations of factor VIII. Factor VIII–deficient plasma is added to each dilution and APTTs are performed according to laboratory protocol. A calibration curve is set up by plotting the known concentration of factor VIII (*x*-axis) against the time to clot in seconds (*y*-axis). This process is repeated, substituting patient plasma for reference plasma. If the patient plasma has decreased levels of factor VIII, it cannot compensate for the absence of factor VIII in the factor VIII–deficient plasma and the time to clot formation is prolonged compared with a similar dilution of reference plasma. By comparing the time to clot of the patient's plasma to the calibration curve, the level of factor VIII activity in the patient's plasma can be quantified.

Immunologic assays can be used to establish the quantity (as opposed to the quality) of coagulation proteins. When used together with clot-based tests, these assays can detect a protein with reduced function, but normal production. For example, an abnormal fibrinogen (dysfibrinogenemia) can be detected by measuring clottable fibrinogen and fibrinogen antigen on the same sample. If fibrinogen clottability (function) is less than 70% of the amount of fibrinogen antigen (production), the protein produced is likely functionally abnormal, however the cut-off for the ratio of activity to antigen is not well validated.

Chromogenic Factor Assays

There has been a significant growth in the development of replacement strategies for hemophilia A and B patients (see Chapter 133). These include extended half-life recombinant factor VIII and factor IX and in the case of FVIII, by-passing agents. The development and increasing use of the new replacement products introduce several challenges for both the clinician and the coagulation laboratory. The APTT-based (one-stage) factor assays are traditionally used for the diagnosis and monitoring of replacement in this patient population. Due to the heterogeneity of the extended half-life products, there is wide and significant variability in the activity levels between one-stage and two-stage or chromogenic factor assays. In response to this, the United Kingdom Haemophilia Centre Doctors' Organisation published a guideline for the laboratory measurement of factor replacement therapies. This guideline summarizes current, as well as soon to be released products and the recommended assay and reagents for laboratories to use.[10] Collaboration between the treating clinicians and the laboratory is paramount to ensure that the appropriate assays for monitoring the replacement products are available.

Evaluation of Specific Inhibitors of Coagulation Proteins

An inhibitor is generally suspected when a prolonged clot-based assay does not correct after mixing patient plasma in equal quantities with normal plasma (i.e., in an immediate 1:1 mix), or if an apparent factor deficiency is not consistent with the patient's clinical history. Screening for inhibitors is accomplished by using a 1:1 mix in a clot-based assay. If coagulation factor–deficient plasma is mixed with normal plasma, clotting will not be impaired, as the normal plasma will compensate for the deficient factor in the plasma and "correct" its prolonged CT. However, if inhibitor-containing plasma is mixed with normal plasma, clotting will be impaired, because the specific inhibitor will decrease the activity of the coagulation factor in the normal plasma as well. Specific inhibitors of coagulation proteins are generally time-dependent, that is, clotting may not be impaired immediately after the 1:1 mix is performed. However, if the mixture is incubated for 2 hours at 37°C, the CT will be prolonged.

Inhibitors of specific coagulation proteins increase the risk for bleeding. The most common acquired inhibitor is an antibody against factor VIII (see Chapters 133 and 134). These can occur as an alloantibody in persons with hemophilia, or as an autoantibody in those with previously normal hemostasis.[11] Patients with an autoantibody-type acquired factor VIII inhibitor present with a prolonged APTT and hemophilia-like bleeding. Both males and females can develop this type of inhibitor. It is characteristically seen in older adult patients, patients with B-cell malignancies, patients with connective tissue disorders such as systemic lupus erythematosus, and in the postpartum period (see Chapter 134). Management decisions in these patients are influenced by the severity of the bleeding and the titer of the inhibitor.[11,12] Quantitative measurement of factor VIII inhibitors is performed using the Bethesda method, often using the Nijmegen modifications for improved sensitivity and specificity. The Bethesda method is based on the observation that if a coagulation factor is incubated with plasma containing its specific inhibitor, the factor will be progressively neutralized. If the amount of factor added and the duration of incubation are standardized, the inhibitor potency can be measured based on how much of the factor is inhibited. One Bethesda unit is defined as the amount of factor VIII inhibitor that will neutralize 50% of 1 unit of factor VIII in normal plasma after 2 hours of incubation at 37°C. Normal pooled plasma is considered to contain 1 unit of factor VIII. The Bethesda assay is performed by incubating dilutions of the patient plasma with normal pooled plasma for 2 hours at 37°C. At the end of the incubation period, the factor VIII and the percentage residual factor activity is calculated and plotted against a standardized lin/log graph of Bethesda units versus residual factor VIII activity. The factor VIII percentage nearest to 50% (between 30% and 60%) is chosen for calculating the potency of the inhibitor to minimize overestimating (<50%) or underestimating (>50%) the inhibitor titre.[12] At 50% residual factor activity, the test plasma contains, by definition, 1 Bethesda inhibitor unit per mL. The Nijmegen modification allows for more accurate determination of inhibitor titers at low levels of factor VIII inhibition. Increases in pH and decreases in protein concentrations can lead to increased inactivation of factor VIII, potentially leading to false-positive results with the standard Bethesda assay. The Nijmegen modification buffers normal plasma with 0.1 M imidazole and uses immunodepleted factor VIII–deficient plasma in the control mixture.

Inhibitors directed against other coagulation factors are rare, and their associated hemorrhagic manifestations are variable, ranging from minor bleeding to life-threatening events (see Chapter 134). Autoantibodies against von Willebrand factor (vWF) can develop in the context of a paraproteinemia, whereas autoantibodies against prothrombin are a rare complication of systemic lupus erythematosus. Inhibitors to other factors can be measured with modifications of the Bethesda method.

Evaluation of Acquired Inhibitors of Coagulation Proteins

The most frequently detected acquired inhibitors are the antiphospholipid antibodies (APLAs) (see Chapter 138). APLAs represent antibodies directed against epitopes on proteins that bind phospholipids. They include the lupus anticoagulant (LAC), anticardiolipin antibodies (aCL), and anti-β_2 glycoprotein I antibodies (aβ_2GPI). LAC are often detected when they interfere with the APTT and PT, which they do to a variable extent. They also interfere in any phospholipid-dependent clotting assay. This effect is dependent on the nature and the concentration of phospholipid in the commercial reagent. LAC (like other APLAs) do not increase bleeding risk. APLAs may have no clinical significance at all, or they may predispose to thrombosis (see Chapter 138). Laboratory assays for APLAs fall into three categories: (1) clot-based assays that detect the LAC; (2) immunoassays that detect aCL; and (3) immunoassays that detect aβ_2GPI. There is currently a lack of standardization of these assays, and their findings do not always correlate with clinical symptoms. However, laboratory identification of APLAs is a key component of diagnosing antiphospholipid syndrome, an autoimmune syndrome that increases the risk of thrombotic and pregnancy complications.[13] Current laboratory principles of detecting APLAs are well described in Chapters 137 and 138. Highlights are outlined here.

LAC screening guidelines recommend the use of two laboratory tests based on different principles: the dilute Russell viper venom time, and a LAC-sensitive APTT, using an APTT reagent containing silica as the activator.[13] Both tests are phospholipid dependent. If at least one of the two tests suggests the presence of a LAC, a 1:1 mixing test using pooled normal plasma should be performed. Confirmatory testing must also be done with an assay that is less sensitive but more specific for LAC by increasing the phospholipid content. aCL and aβ_2GPI antibodies are detected using immunoassays. Traditionally, the ELISA technique was used. However, newer automated assays have been introduced; these are expected to improve test reproducibility, specificity, and accuracy of detection. At this time, aCL and aβ_2GPI testing is not well standardized, and there is a lack of uniformity in reference material used for calibration. Reporting is also not standardized. aCL assays are expressed in GPL (units of aCL immunoglobulin [Ig] G antibodies, calculated against the original Harris standards) or MPL (units of aCL IgM antibodies, calculated against the original Harris standards). aβ_2GPI can be expressed in U/mL, ng/mL, and μg/mL among others.

PRACTICAL APPROACH TO LABORATORY TESTING OF COAGULATION PROTEINS

The first step in interpreting laboratory tests of coagulation proteins is synthesizing the results of the PT, APTT, and TCT. When all three assays are performed simultaneously, they can give the clinician a high-level snapshot of the patient's coagulation factors, and inform a practical differential diagnosis (Table 127.1). An abnormality in one test suggests an abnormality in one branch of the Ratnoff-Davie-Macfarlane coagulation cascade, whereas abnormalities in more than one test suggest a problem in the common pathway of coagulation.

Isolated prolongation of the APTT is caused by abnormalities in the intrinsic pathway, only some of which are associated with an increased bleeding risk (see Table 127.1). It is essential to consider the APTT in the context of a thorough clinical bleeding assessment (see Chapter 126). If the prolonged APTT is associated with bleeding, then the differential diagnosis in decreasing likelihood of frequency is factor VIII deficiency; factor IX deficiency; or factor XI deficiency. Factor VIII and IX deficiencies are X-linked, and affect 1:5000 to 10,000 males and 1:25,000 to 30,000 females respectively.[14] Factor XI deficiency is an autosomal disorder that affects both males and females, and has a variable prevalence.[14] It causes a clinically significant bleeding disorder in 1 in 1 million individuals in the general population, but has a rate of heterozygosity as high as 8% to 9% in Ashkenazi Jews (see Chapters 133 and 134 for a full discussion of these factor deficiencies). If the isolated prolonged APTT is not associated with bleeding symptoms, the most common cause is an APLA, often found in otherwise healthy individuals. Coagulation protein deficiencies that prolong the APTT but are not associated with bleeding include factor XII, prekallikrein, and high-molecular-weight kininogen deficiency (see Table 127.1). It is important to consider these three proteins when evaluating isolated prolongation of the APTT to preclude misguided attempts to "correct" the prolonged APTT by giving patients unnecessary blood products or factor concentrates.

Isolated prolongation of the PT is caused by abnormalities in the extrinsic pathway (see Table 127.1). An isolated PT prolongation associated with bleeding usually indicates factor VII deficiency (see Chapter 134); these deficiencies are partial, as complete factor VII deficiency appears to be incompatible with life.[14] Sometimes, mild defects in common pathway proteins (e.g., factors II, V, and X) may initially appear as an isolated PT prolongation, though as they progress, they eventually prolong the APTT as well. This asynchronous prolongation occurs because PT reagents with an ISI approaching 1 are more sensitive to factor deficiencies, specifically factors VII, X, and II, than the APTT reagents. Conversely, the PT and APTT are relatively insensitive to mild defects in fibrinogen. With some reagents, APLAs may also prolong the PT.

When confronted with prolongation in both the PT and APTT, the hematologist should first consider clinical situations that broadly affect these tests: anticoagulant therapy, vitamin K deficiency, liver disease, or disseminated intravascular coagulation (DIC) (see Table 127.1). These conditions are far more common than isolated deficiencies of the factors in the common pathway (factors II, V, and X). Anticoagulants act by inhibiting one or many coagulation proteins in the common pathway, while vitamin K deficiency decreases the functional levels of factors II, VII, IX, and X. Vitamin K deficiency is

TABLE 127.1 **Synthesizing Results of Prothrombin Time, Activated Partial Thromboplastin Time, and Thrombin Clotting Time**

Test				
PT	**APTT**	**TCT**	**Possible Diagnoses**	**Next Steps**
N	N	N	Normal hemostasis, disorder of platelet function, factor XIII deficiency, disorder of vascular hemostasis, mild coagulation protein deficiency, mild vWD, disorder of fibrinolysis (α_2-antiplasmin deficiency/defect, plasminogen activator inhibitor-1 deficiency/defect)	Focused history and physical, medication review, evaluation of platelets, evaluation of fibrinolysis, evaluation of vWF
H	N	N	Factor VII deficiency, early oral anticoagulation, lupus anticoagulant (reagent dependent), mild factor II, V, or X deficiency, specific factor VII inhibitor	Focused history and physical, medication review, factor assays (VII, II, V, X), evaluation of specific factor inhibitor, evaluation of antiphospholipid antibodies
N	H	N	Factor VIII, IX, XI, XII, prekallikrein or HMWK deficiency, lupus anticoagulant, amyloid-adsorbed factor IX, specific factor inhibitor	Focused history and physical, factor assays (VIII, IX, XI, XII, PK, HMWK), evaluation of specific factor inhibitor, evaluation of antiphospholipid antibodies, evaluation of amyloidosis (initially, serum and urine protein electrophoresis with immunofixation, serum free light chain assay)
H	H	N	Multiple factor deficiency (e.g., liver failure, vitamin K deficiency, oral anticoagulants), factor V, X, or II deficiency, amyloid-adsorbed factor X, specific factor inhibitor	Focused history and physical, medication review, factor assays (V, X, II), evaluation of specific factor inhibitor, evaluation of liver productive function and liver injury (albumin, ALT, AST, GGT, alkaline phosphatase), evaluation of amyloidosis (initially, serum and urine protein electrophoresis with immunofixation, serum free light chain assay)
H	H	H	Anticoagulants, DIC, dilutional coagulopathy, liver disease, severe fibrinogen deficiency/disorder, inhibition of fibrin polymerization, hyperfibrinolysis	Focused history and physical, medication review, clottable fibrinogen and fibrinogen antigen, reptilase time, evaluation of fibrinolysis, evaluation of liver productive function and liver injury (albumin, ALT, AST, GGT, alkaline phosphatase)

ALT, Alanine aminotransferase; *APTT*, activated partial thromboplastin time; *AST*, aspartate aminotransaminase; *DIC*, disseminated intravascular coagulation; *GGT*, gamma glutamyltransferase; *H*, high/prolonged; *HMWK*, high-molecular-weight kininogen; *N*, normal; *PT*, prothrombin time; *TCT*, thrombin clotting time; *vWD*, von Willebrand disease; *vWF*, von Willebrand factor.

found in individuals receiving warfarin therapy, who are profoundly nutritionally depleted (caused by poor diet or the receipt of incomplete parenteral nutrition), who have altered gut microbiota as a result of intestinal surgery or antibiotic therapy, or, very rarely, who have defects in transport proteins or enzymes for vitamin K metabolism. The liver synthesizes most of the coagulation proteins, so liver disease can have a profound effect on laboratory tests of hemostasis by causing multiple factor deficiencies. Prekallikrein, factor XI, factor VII, and factor V production drop in hepatic failure, and fibrinogen synthesis becomes abnormal. DIC, an important cause of APTT and PT prolongation, is discussed in detail toward the end of this chapter (see also Chapter 136).

TCT prolongation can be caused by reduced fibrinogen levels (e.g., because of liver disease), abnormal fibrinogen function, or large amounts of thrombin inhibitors like heparin or a direct thrombin inhibitor. The TCT also detects defects in fibrinopeptide A and B release, as well as polymerization defects. The reptilase time uses Batroxobin (Reptilase), a purified enzyme from the snake *Bothrops atrox*, to "clot" fibrinogen by liberating only fibrinopeptide A. An abnormal TCT with a normal reptilase time indicates a fibrinopeptide B–release defect, an abnormality that results in long APTT and PT values but is not associated with bleeding. The reptilase time will not be altered by the presence of heparin and can thus be used to determine if a prolonged TCT is the result of heparin. Another practical way to determine if a prolonged TCT is a result of heparin is to use the protamine neutralization test. This test is based on the TCT, with varying amounts of protamine sulfate added to patient plasma before the addition of thrombin. Protamine sulfate can neutralize heparin, and thus normalize the TCT. The concentration of heparin in the plasma can be calculated from the amount of protamine sulfate required to neutralize the heparin.

When presented with a prolonged clot-based assay, the hematologist must also be able to differentiate between a coagulation protein deficiency and an inhibitor to a specific coagulation protein. Two approaches can be used to obtain a specific diagnosis. The first approach uses the immediate 1:1 mix, a test in which patient and normal pooled plasma are mixed in equal proportions. Mixing studies based on the PT or APTT are interpreted based on the fact that 50% levels of any coagulation factor will yield normal PT and APTT values. Only when the level drops below 50% will clot formation become prolonged, though the sensitivity of the assay then depends on the factor and the test reagent. Practically, this means that if a patient has less than 1% of a factor, and their plasma is mixed 1:1 with normal plasma, the PT or APTT will correct to normal. However, if a patient has something in their plasma that interferes with protein function in normal plasma (e.g., an inhibitor, an anticoagulant), the PT or APTT will remain prolonged. The immediate 1:1 mix can thus be used to screen for the presence of factor deficiency and inhibitors. This approach is far from perfect. No studies provide standardized evidence-based laboratory procedures for these screening assays, so the ratio of patient plasma to normal plasma used, the time of incubation from mixing to assay, and the sensitivity and specificity for assessing factor deficiencies and circulating anticoagulants are variable. This makes it difficult to translate the results of mixing studies into meaningful diagnostic data. If a factor deficiency or inhibitor is suspected, it is essential to perform the appropriate specific testing, as outlined previously.

Other comorbid illnesses may also result in a bleeding diathesis. For example, systemic amyloidosis is associated with decreases in plasma factor X or IX because of adsorption of the coagulation proteins onto the amyloid protein. In the case of factor X adsorption, the PT and APTT may be affected, while in the case of factor IX adsorption, only the APTT is affected. Hypergammaglobulinemic states seen with multiple myeloma or Waldenström macroglobulinemia (IgM) can be associated with inhibitors to coagulation protein function. Dysfibrinogenemias are common in these patients because fibrinogen readily binds the immunoglobulin.

LABORATORY EVALUATION OF PLATELETS AND VON WILLEBRAND FACTOR

Screening for Disorders of Primary Hemostasis

Disorders of platelets and vWF, the key components of primary hemostasis, are characterized by disproportionate bleeding after injury or surgery, petechiae, purpura, ecchymoses, mucosal bleeding (including epistaxis and gum bleeding), and heavy menstrual bleeding. Most patients have a family history of similar mucocutaneous bleeding. In the past, the Ivy bleeding time—a test in which the forearm is cut, and the time until bleeding stops is measured—was used to screen for disorders of primary hemostasis, including platelet function disorders (PFDs) and von Willebrand disease (vWD).[15] This test is no longer considered to be useful in the investigation of bleeding disorders. Bleeding times are invasive and operator dependent, can be affected by nonhematologic factors (e.g., Ehlers-Danlos syndrome, osteogenesis imperfecta, scurvy, skin quality, skin temperature, vascular function), and have low predictive value for surgical bleeding.[16] Bleeding times also are not useful for detecting platelet dysfunction in the setting of thrombocytopenia. Importantly, the bleeding time is neither sensitive nor specific enough to preclude further testing for vWF or platelet abnormalities.[17] A normal bleeding time should not reassure the clinician that an important bleeding disorder is not present.

Several automated analyzers have been proposed as replacements for the bleeding time, and potentially useful screening tools for disorders of primary hemostasis. The platelet function analyzer (PFA-100, Siemens, Deerfield, IL) has been best evaluated. The PFA-100 attempts to recreate the high shear conditions under which primary hemostasis occurs in vivo. Using citrated whole blood, it measures the closure time required for platelets to adhere to agonist-coated membranes and aggregate under high shear stress (5000 to 6000/s). Two cartridges are available: one with collagen–adenosine diphosphate (ADP) membranes, and the other with collagen–epinephrine coated membranes. Platelet function is measured as a function of the time needed to occlude the aperture, termed the *closure time*. Abnormalities can lead to prolongation of the closure time. The PFA-100 is more sensitive than the bleeding time in patients with previously diagnosed vWD, but less sensitive in those with mild platelet secretion disorders (which are the most frequent PFDs) and platelet storage pool deficiency. In a prospective study by Quiroga et al., the overall sensitivity of closure times in vWD and PFDs were 50% and 18%, respectively.[17] This suggests that the PFA-100 is only marginally more useful than the bleeding time. It is still not sensitive or specific enough to preclude further testing for vWF or platelet abnormalities and cannot definitively rule out important bleeding disorders.

At this time, laboratory screening tests for disorders of primary hemostasis have limited usefulness. Diagnosis of these disorders must be grounded in a thorough clinical history and physical examination, and ultimately relies on the performance of the specific and sensitive tests outlined in the following.

Evaluation of Platelets

The first step in the investigation of platelet disorders is determining the platelet count because thrombocytopenia alone may increase bleeding risk (thrombocytopenia is discussed in detail in Chapters 128 and 129). Obtaining a detailed list of medications the patient is taking, allopathic and naturopathic, prescription and over-the-counter, is also essential, as many drugs impact platelet number and function. Platelet function can also be altered in the setting of systemic disorders, such as chronic kidney disease, liver disease, myeloproliferative and myelodysplastic disorders, and malignancy. Inherited platelet disorders are often syndromic, and are associated with manifestations like albinism, bone changes, sensorineural hearing loss, renal disease, and immunodeficiency (see Chapter 126).

Platelet function can be evaluated with platelet aggregation studies. These tests measure the ability of agonists to cause in vitro platelet activation and aggregation. Two forms of platelet aggregation studies are available: light transmission aggregometry (LTA) in platelet-rich plasma and impedance aggregometry in platelet-rich plasma or whole blood. LTA in platelet-rich plasma is considered the gold standard for platelet function testing, whereas impedance aggregometry is less well characterized. Several recent guidelines have laid out standards on how to perform and interpret LTA.[18] Briefly, when a platelet agonist is added to platelet-rich plasma, aggregation occurs and light transmission increases. When factors like temperature, platelet count, and mixing speed are controlled, the amount and rate of this increase depends on how reactive platelets are to the added agonist. The increase in light transmission can be measured spectrophotometrically. Recommended agonists include ADP, epinephrine, arachidonic acid, collagen, and the thromboxane analogue U46619 at predetermined concentrations.[18] Ristocetin, an antibiotic that facilitates vWF binding to the glycoprotein Ib/IX/V complex, is also used in LTA to induce platelet agglutination. ADP and epinephrine induce a biphasic aggregation pattern; primary aggregation occurs in response to activation of the platelet glycoprotein IIb/IIIa receptor, then platelets degranulate and there is secondary aggregation. Conversely, arachidonic acid, thromboxane analogue, and collagen result in a monophasic aggregation pattern (see Chapter 123). Several defects of platelet function have well-characterized LTA patterns (Fig. 127.4).[19] Bernard–Soulier syndrome, a defect in glycoprotein Ib, results in normal aggregation to ADP and collagen, but absent agglutination to ristocetin (this pattern can also be seen in vWD.) Glanzmann thrombasthenia, a defect in glycoprotein IIb/IIIa, results in an absent primary response to ADP and collagen (see Chapter 123). Impaired aggregation to arachidonic acid suggests an aspirin effect, or cyclooxygenase deficiency. The abnormal arachidonic acid response can be further delineated with the use of thromboxane analogue U46619 (see Chapter 127). Platelet storage pool disorders can be diagnosed with LTA and studies that measure proteins within or released from platelet α-granules or dense granules. Tests of ATP secretion from platelets can complement and expand on LTA results, however reproducibility of these findings is poor.[20] ATP secreted by dense granules is measured using a sensitive luminescent (firefly luciferin-luciferase) assay for extracellular ATP. Platelet electron microscopy is increasingly used to evaluate the ultrastructure of platelets, including the dense granules. Finally, with appropriate monoclonal antibodies, flow cytometry can examine the surface of the platelet. Flow cytometry has a variety of uses, including detection of platelet activation by using antibodies to proteins expressed on the platelet surface (e.g., P-selectin, thrombospondin), diagnosis of platelet surface glycoprotein deficiencies, and measurement of dense granules (see Chapter 123).

Evaluation of von Willebrand Factor

vWD is discussed in detail in Chapter 132. It is diagnosed when patients have a history of mucocutaneous bleeding (usually with a positive family history), and quantitative or qualitative abnormalities of vWF. Laboratory testing for vWD includes the factor VIII assay, vWF antigen (vWF:Ag), and vWF activity (commonly measured with the ristocetin cofactor assay, vWF:Rco or with an automated assay).[21] Many laboratories also test vWF further with the collagen binding assay (vWF:CB), which is abnormal when there is a loss of high-molecular-weight vWF multimers or impaired binding of vWF to the vascular endothelium, the low-dose ristocetin-induced platelet aggregation assay (abnormal with loss-of-function and gain-of-function defects that characterize type 2B vWD and platelet-type pseudo-vWD), and vWF multimer analysis (which is useful in type 2A and 2M vWD).[21] Assays that measure factor VIII binding to vWF can identify patients with defects in factor VIII binding, such as type 2N vWD.[21] Highly specialized coagulation laboratories may also perform vWF gene sequence analysis and vWF propeptide analysis; the latter shows promise in detecting defects associated with accelerated vWF clearance (see Chapter 132).[21]

The diagnosis of vWD, particularly type 1 vWD, which is defined as a partial, quantitative deficiency of vWF, can be challenging.[15]

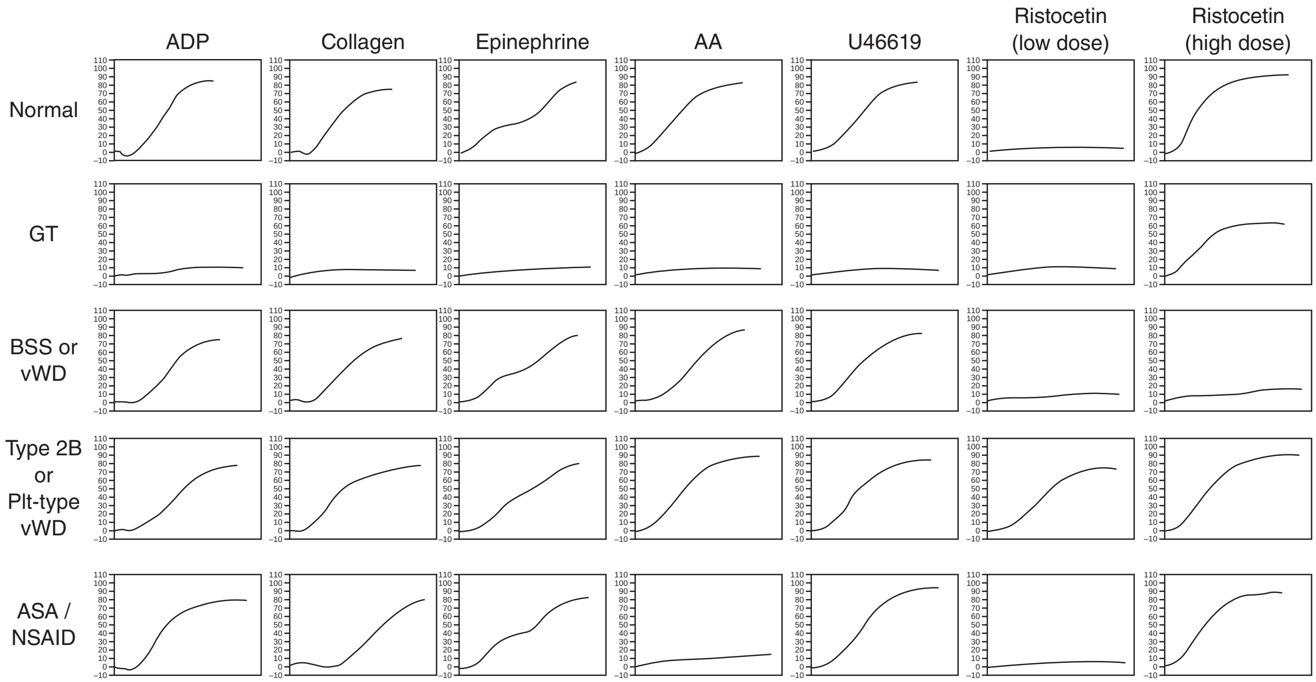

Figure 127.4 LIGHT TRANSMISSION AGGREGOMETRY PATTERNS. In Glanzmann thrombasthenia (GT) aggregation is absent or decreased with all agonists except high dose ristocetin. In Bernard-Soulier syndrome (BSS) and von Willebrand disease (vWD) there is an aggregation response with all agonists except ristocetin. In the presence of acetylsalicylic acid (ASA) or nonsteroidal antiinflammatory drugs (NSAID) aggregation is reduced with arachidonic acid (AA) but present with thromboxane analogue U46619. *ADP*, Adenosine diphosphate.

Studies have shown a high prevalence of bleeding symptoms in normal, healthy individuals. By definition, 2.5% of the population will also have a level of vWF:Ag that falls below the lower limit of laboratories' normal reference range. Thus, there is a danger of coincidentally associating low vWF with bleeding symptoms, and overdiagnosing type 1 vWD in the general population.[22] To further complicate matters, the normal range of plasma vWF is quite broad. vWF is an acute phase reactant, and can increase in patients with inflammation, infection, or stress. Levels also increase with pregnancy and with comorbid diseases like cancer. vWF levels increase with age and are lower in individuals with blood type O (see Chapter 132). It is recommended that the label of type 1 vWD only be applied when the clinical presentation is consistent, and when vWF levels are persistently low and <30 IU/dL.[15]

LABORATORY EVALUATION OF FIBRINOLYSIS

Disorders of fibrin cross-linking and fibrinolysis are not recognized with routine coagulation and platelet testing (see Table 127.1). Congenital factor XIII deficiency, a rare disease with a prevalence of 1 in 2 or 3 million people worldwide, is one example.[23] Screening tests for factor XIII deficiency aim to denature fibrin clots in acetic acid, monochloroacetic acid, or urea.[23] In the urea clot solubility test, clot formation is induced in patient plasma and in normal and factor XIII deficient plasma controls by addition of calcium with or without added thrombin. Clots are exposed to a 5 M urea solution and observed over time. The control clot should remain undissolved at 24 hours because fibrin clots cross-linked in the presence of thrombin and factor XIII are stable. If the patient has severe factor XIII–deficiency, the clot will dissolve rapidly. The urea clot solubility test and related assays are not standardized and have poor sensitivity; their detection limit is generally less than 5% of factor XIII activity. Suspected factor XIII deficiency must be confirmed by functional assays (which measure the release of ammonia during the transglutaminase reaction or incorporation of radioactive amines into proteins), or immunologic factor XIII antigen assays (see Chapter 134).[23]

Tests that provide a global picture of fibrinolysis can also be performed; they measure the combined effect of plasminogen activators (e.g., urokinase, tissue plasminogen activator) and inhibitors (e.g., α_2-antiplasmin, plasminogen activator inhibitor-1 [PAI-1]). Defects in the latter group of proteins can produce hyperfibrinolytic states and increased bleeding potential. In the euglobulin clot lysis assay, plasma is diluted and acidified at 4 °C. This causes precipitation of the acid insoluble or euglobulin fraction of plasma, which includes fibrinogen, plasminogen, plasminogen activators, and PAI-1. The precipitate is redissolved, and the fibrinogen is clotted by adding calcium. The time to spontaneous lysis of the fibrin clot is then monitored. Shortened lysis times are observed in hyperfibrinolytic states such as DIC, or when there is a deficiency of PAI-1; however, like the urea clot solubility test, the euglobulin clot lysis time is hampered by a lack of standardization and susceptibility to interference by other factors. Specialized coagulation laboratories may offer specific assays for plasminogen inhibitors as well.

OTHER ACTIVITIES FOR HEMOSTASIS LABORATORIES

Global Hemostasis Assays

Standard coagulation tests can measure the individual components of hemostasis. There is tremendous interest in evaluating hemostasis more globally, to accurately evaluate in vivo hemostatic function, sensitively and specifically diagnose hemostatic disorders, monitor treatment, and better predict clinical manifestations of disordered hemostasis. Global hemostasis assays aim not only to measure components of hemostasis, but also determine how they interact with each other. They do so by assessing the rate of thrombin generation, the quantity of thrombin generation, the formation of clots in whole blood, and/or the polymerization of fibrin.

Measurement of thrombin generation was first described in the early 1950s by MacFarlane and Biggs (who used whole blood), and

Pitney and Dacie (who used plasma). Over the years, methods were refined; ultimately, continuous measurement of thrombin generation was accomplished by using a thrombin-chromogenic substrate in defibrinated plasma, or a fluorogenic substrate in whole plasma. In general, modern thrombin generation assays (TGAs) use recalcified platelet-rich or platelet-poor plasma, and then trigger clotting with tissue factor. TGAs can capture not only the rate and amount of thrombin generated, but also the role of platelets (which act as an amplifying surface for thrombin generation) if they are performed in platelet-rich plasma. TGAs have been widely used in research. Clinically, they may play a role in thrombophilic states (e.g., antithrombin deficiency, protein C or S deficiency, activated protein C resistance, cancer-associated thrombosis) and in hemorrhagic tendencies (e.g., hemophilia, other factor deficiencies, cardiac surgery). In hemophilia, TGAs might more accurately predict bleeding risk and efficacy of inhibitor bypassing than traditional tests. TGAs are not yet used broadly in the clinical context; test procedures are not well standardized, and validated reference ranges for specific conditions have not been developed.

Viscoelastic assays like thromboelastography and thromboelastometry are increasingly used in the clinical context. Viscoelastic tests are based on the premise that the result of normal hemostasis is to rapidly create a strong, stable clot; changes in the speed of clot formation, or its strength or stability, may indicate abnormal hemostatic function. Thromboelastography was first described in 1948 by Hartert, who presented a method in which clotting was triggered in fresh whole blood with the addition of celite (an activator of the intrinsic pathway). The blood was then put into a continuously rotating cup, and a torsion wire was introduced into the system. As the clot gradually became stronger, the movement of the torsion wire dampened and ultimately stopped. A tracing of the torsion wire's movement over time reflected the velocity of clot formation, its maximal stability, and its gradual dissolution. This tracing was recorded onto light-sensitive photographic paper by a mirror-galvanometer; the image developed over hours to days.

Currently, two semi-automated commercially available viscoelastic devices allow results to be obtained in 10 to 15 minutes: the ROTEM-analyzer (TEM International, Munich, Germany), which uses a fixed cup with a rotating pin and optical detector, and the TEG-analyzer (Haemonetics Corp., Braintree, MA), which uses a torsion wire and a rotating cup. Both are kinetic tests, and their tracings measure clot formation over time. They also measure maximal clot strength, clot elasticity, and clot lysis. Both use citrated whole blood that is recalcified and added to a cuvette. An activator (e.g., tissue factor) is commonly used to standardize the test and speed up the assay. These analyzers can perform additional tests (using different activators or additives) to provide information like that of the APTT or PT, to neutralize heparin, to inhibit fibrinolysis, and to qualitatively analyze the functional fibrinogen component.

A TEG tracing has several components (Fig. 127.5). Initial clot formation, and the activity of coagulation factors, is captured by the reaction (R) time. As the clot forms, the TEG measures the kinetic (K) time, which reflects the interaction of coagulation factors, fibrin, and platelets. The maximal amplitude (MA) reflects platelet function and fibrinolysis. Once the clot begins to break down, the TEG gives information on lysis at 30 and 60 minutes (CL30 and CL60, respectively). These components reflect fibrinolysis. A ROTEM tracing provides similar information; the CT, clot formation time (CFT), maximum clot formation (MCF), and lysis time (LY) are essentially interchangeable with the R time, K time, MA, and CL, respectively.[24]

Viscoelastic methods are increasingly used at the bedside.[24] They have shown some promise in detecting coagulopathies and guiding the use of blood products and other prohemostatic therapy intraoperatively, in obstetric hemorrhage, in the trauma setting, and in the intensive care unit.[25] They may also be helpful in screening for hypercoagulable states, as some individuals with a history of thromboembolism demonstrate accelerated clot propagation. Viscoelastic methods do have some drawbacks. They are insensitive to platelet and vWF dysfunction, as well as to factor XIII problems. Assay standardization and variability of results continue to be a challenge.[26,27]

Figure 127.5 COMPONENTS OF A TEG (thromboelastogram) TRACING AND EXAMPLES OF DISORDERED COAGULATION. Initial clot formation and the activity of coagulation factors is captured by the reaction (R) time. The interaction of factors, fibrin, and platelets is captured by the kinetic (K) time. Platelet function and fibrinolysis are captured by the maximal amplitude (MA). Once the clot begins to break down, the TEG gives information on lysis at 30 and 60 minutes. Various disorders of coagulation can be detected using the TEG.

Evaluation of Prothrombotic States

In addition to the diagnosis of bleeding disorders, the hemostasis laboratory can help evaluate acquired and inherited prothrombotic states (see Chapter 137). It is known that certain prothrombotic states (e.g., antithrombin, protein C, and protein S deficiencies; antiphospholipid syndrome) may confer a higher risk for recurrent thrombosis. Patients with these abnormalities may benefit from long-term anticoagulation after their first episode of thrombosis. Less severe prothrombotic states (e.g., heterozygous factor V Leiden and prothrombin 20210 polymorphisms, functional defects in fibrinogen and plasminogen) do not appear to impact the risk of recurrence. Clinicians often consider testing for prothrombotic states in patients who develop thrombosis at a young age, who have a strong family history of thrombosis, who have thrombosis at an unusual site, or who experience recurrent or unexplained thrombosis. However, the utility of this testing is limited, as the results usually do not affect patient management or result in improved patient outcomes.[28] Testing can also result in potential harm, including inappropriate use of anticoagulation and undue patient anxiety. For these reasons, testing for prothrombotic states is not routinely recommended in unselected patients with thrombosis. Testing should only be undertaken with patients whose clinical presentation strongly suggests an underlying prothrombotic condition. Before testing is done, clinicians should consider how it will affect management, and if it is aligned with the patient's values and preferences. Clinicians should also understand the effect of anticoagulants on commonly ordered coagulation tests, to ensure results are not misinterpreted (Table 127.2).

Monitoring Anticoagulant Therapy

The coagulation laboratory plays an important role in the monitoring of patients on anticoagulant therapy (see Table 127.2). Historically, monitoring was limited to unfractionated heparin and warfarin, which are monitored using the clot-based APTT and PT/INR assays, respectively. However, coagulation laboratories are increasingly developing assays to monitor low-molecular-weight heparin (LMWH), fondaparinux, parenteral direct thrombin inhibitors, and the direct oral anticoagulants (DOACs), which include dabigatran, rivaroxaban, apixaban, and edoxaban (see Chapter 142). Therapeutic ranges for these agents are not clinically validated and may vary by laboratory and by indication. However, clinicians may consider measurement of on-therapy drug levels in patients who are obese, have kidney or hepatic insufficiency, experience thrombosis or bleeding while on therapy, or require urgent surgery.

The ability to neutralize the enzymatic activity of factor Xa or thrombin is the most reliable method to quantify the plasma levels of anticoagulants. Anti-factor Xa chromogenic assays can be used to measure factor Xa inhibitors like LMWH, fondaparinux, rivaroxaban, apixaban, and edoxaban, while anti-IIa (thrombin) or ecarin based chromogenic and clot-based assays can measure direct thrombin inhibitors like argatroban, bivalirudin, hirudin, and dabigatran. Standard curves for anticoagulants are constructed by combining known amounts of the anticoagulant and the factor it inhibits. Residual factor activity is inversely proportional to the concentration of drug in the sample. Anti-factor Xa assays to monitor LMWHs can be developed against WHO's International Standard for LMWH,

TABLE 127.2 **The Effect of Anticoagulants on Commonly Ordered Coagulation Tests**

Test	Warfarin	UFH	LMWH	Direct Thrombin Inhibitors (e.g., Dabigatran)	Factor Xa Inhibitors (e.g., Rivaroxaban, Apixaban, Edoxaban)
PT/INR (clot based)	Increases	No effect or increases	No effect	No effect or increases	No effect or increases
APTT (clot based)	Increases	Increases	No effect or increases	No effect or increases	No effect or increases
Thrombin time (clot based)	No effect	Increases	No effect or increases	Increases	No effect
Clauss fibrinogen (clot based)	No effect	No effect	No effect	Minimal effect to falsely decrease (if direct thrombin inhibitor level very high)	No effect
Antithrombin (chromogenic anti-Xa based)	No effect	Decreases	No effect to decreases	No effect	Falsely increases
Antithrombin (chromogenic anti-IIa based)	No effect	Decreases	No effect to decreases	Falsely increases	No effect
Protein C—functional (clot based)	Decreases	No effect (neutralizer in reagent)	No effect	Falsely increases	Falsely increases
Protein C—functional (chromogenic)	Decreases	No effect (neutralizer in reagent)	No effect	No effect	No effect
Protein S—free (latex immunoassay)	Decreases	No effect	No effect	No effect	No effect
Activated protein C (APC) resistance (clot based)	Unknown	Unknown	Unknown	Unknown, may be falsely normal	Unknown, may be falsely normal
Lupus anticoagulant—lupus sensitive APTT (clot based)	Falsely increases, may correct on mixing	Falsely increases, generally does not correct on mixing	Possibly falsely increases, generally does not correct on mixing	Falsely increases, generally does not correct on mixing	Falsely increases, generally does not correct on mixing
Lupus anticoagulant—DRVVT (dilute russell viper venom time) (clot based)	Falsely increases, does not correct on mixing	No effect	No effect	Falsely increases, does not correct on mixing	Falsely increases, does not correct on mixing

APTT, Activated partial thromboplastin time; *INR*, international normalized ratio; *PT*, prothrombin time.

which serves as a calibrator of drug levels. Other anticoagulants require unique calibrated assays.[29]

The DOACs also affect more commonly used clot-based assays. The TCT and APTT are more sensitive to dabigatran than the PT, and the TCT can be used to exclude the presence of dabigatran and its anticoagulant effect. The PT is sensitive to rivaroxaban (though sensitivity varies by laboratory reagent), while it is less sensitive to apixaban.[30] The PT should not be used to exclude clinically significant drug concentrations of either rivaroxaban or apixaban; appropriately calibrated anti-factor Xa assays are more appropriate.

It is important to understand the effect of anticoagulants on commonly ordered coagulation tests, not just to estimate their drug concentrations, but to ensure that these test results are not misinterpreted due to the presence of interfering drugs (see Table 127.2).

Evaluating Activated Coagulation States

Specialized coagulation laboratories can monitor activated coagulation states that result in acute hemostasis and thrombosis, such as antiphospholipid syndrome (see Chapter 138), heparin-induced thrombocytopenia (see Chapter 130), and warfarin–induced skin necrosis (see Chapter 142). The classic activated coagulation state is DIC (see Chapter 136). DIC is a clinicopathologic state characterized by excessive and dysregulated activation of coagulation and fibrinolysis, with consequent consumption of prothrombotic and antithrombotic factors. DIC is triggered by an underlying cause, such as sepsis, malignancy, trauma, obstetrical complications, or intravascular hemolysis. There are two forms of DIC: an *acute* and a *chronic* form. The acute form is characterized by overwhelming defibrination and a tendency to hemorrhage. The APTT and PT are elevated, and the fibrinogen level and platelet count are low. The more indolent chronic form is characterized by partially compensated coagulation and a tendency to thrombosis. The APTT, PT, and platelet count may be normal or slightly low, and the fibrinogen can be normal or even elevated.

The laboratory diagnosis of DIC requires evidence of simultaneous coagulation and fibrinolysis. Evaluation begins with a complete blood count, PT, APTT, and fibrinogen. The D-dimer assay is a useful adjunct to confirm fibrinolysis. D-dimers are insoluble degradation products that arise when fibrin is cross-linked by thrombin-activated factor XIII, and then degraded by plasmin. Though D-dimer elevation is a sensitive test for DIC, it is not specific for this condition; D-dimer elevation occurs in pregnancy, large vessel thrombosis, hepatic failure, and many other conditions. Isolated D-dimer elevation in the absence of another etiology can also suggest chronic DIC. Laboratory testing can be repeated serially to monitor the severity of DIC, and its response to treatment.

CHAPTER 128

ACQUIRED DISORDERS OF PLATELET FUNCTION

Peter L. Gross and José A. López

Acquired disorders of platelet function are among the most common hematologic abnormalities, which reflects the sensitivity of platelets to external and internal perturbations. The clinical challenge in evaluating acquired disorders of platelet function is to determine whether observed derangements in platelet function pose a threat to the patient. Although altered platelet function can predispose patients to either hemostatic or thrombotic disorders, this chapter deals primarily, but not exclusively, with platelet disorders that may compromise hemostasis. We also try to help clinicians determine the clinical importance of these disorders, but the marked variation in bleeding risks associated with disorders of platelet function renders this a difficult task. Bleeding in patients with acquired platelet dysfunction is likely to occur less frequently and predictably than in those with severe inherited platelet disorders such as Bernard-Soulier syndrome or Glanzmann thrombasthenia (see Chapter 123) and may manifest only in the setting of trauma or surgery or in the presence of additional hemostatic defects. However, even some patients with inherited platelet disorders only bleed when stressed by surgery or trauma, making the distinction between inherited and acquired disorders less clear-cut.

The laboratory evaluation of these patients may illuminate these disorders (see Chapter 126) but may offer little concrete guidance in management. Acquired platelet defects (Table 128.1) may produce abnormal laboratory test results, such as a prolonged closure time on a platelet function analyzer (PFA) or abnormal aggregation in response to added agonists. Historically, the bleeding time was used to evaluate bleeding risk in patients with jaundice or uremia, but it measures hemostasis only in one vascular bed (the skin) and bears inherent inter-operator variability. Although platelet assays are useful research tools, defects quantified by laboratory tests, including the bleeding time, are not predictive of bleeding in these patients. Additionally, some acquired platelet disorders increase the risk of thrombosis rather than bleeding, a risk for which there is currently no effective screening test. Lastly, tests that depend on assessment of the function of platelets ex vivo do not assess the contributions of labile substances from the endothelium (see Chapter 122) and occasionally (as in platelet aggregometry) do not account for flow, a key component of in vivo platelet function.

DRUGS, FOODS, AND ADDITIVES THAT AFFECT PLATELET FUNCTION

The most common causes of acquired platelet dysfunction are drugs. In a large prospective study, 5649 unselected adult patients were screened preoperatively for hemostatic defects with the activated partial thromboplastin time (aPTT), prothrombin time (PT), platelet count, PFA-100 testing, and a questionnaire regarding bleeding history.[1] Bleeding history was positive in 628 patients (11.1%), and impaired hemostasis was verified in 256 (40.8%) of these patients. Of these 256 patients, 162 (63.28%) were found to have acquired platelet dysfunction. Antiplatelet drugs or nonsteroidal anti-inflammatory drugs (NSAIDs) were responsible for the acquired platelet dysfunction in 147 patients and antibiotics were responsible in 10 patients.

Numerous drugs affect platelet function (Table 128.2). For several, inhibition of platelet function is their intended effect; for most, platelet dysfunction is an unintended and undesired side effect. Drug-induced platelet function abnormalities do not usually cause a clinically significant problem in healthy individuals. However, these drugs may increase the bleeding risk with interventions (e.g., surgery, biopsy), trauma, or in the presence of other hemostatic defects, such as those associated with cirrhosis or uremia. Antiplatelet agents are discussed more fully in Chapter 143 The effects of these drugs on platelet function are defined by abnormalities of platelet aggregation, but their contribution to a risk of excessive bleeding is definitively established only for acetylsalicylic acid (ASA, aspirin), clopidogrel, prasugrel, ticagrelor, inhibitors of glycoprotein IIb/IIIa, and vorapaxar.

ANTIPLATELET DRUGS

Activation Receptor Antagonists

Adenosine Diphosphate (ADP) Receptor Antagonists

The thienopyridines selectively and irreversibly inhibit ADP-mediated platelet activation and aggregation.[2] ADP activates platelets by raising the concentration of cytoplasmic Ca^{2+} through influx from the extracellular fluid and mobilization from internal stores, and by decreasing the concentration of intracellular cyclic adenosine monophosphate (cAMP) coupled to inhibition of adenylyl cyclase. ADP receptors can be divided into two groups: the G protein–coupled receptors, termed P2Y, and the ionotropic receptors, P2X. Platelets contain two P2Y receptors, $P2Y_1$ and $P2Y_{12}$, complexed to the heterotrimeric G proteins G_q and G_{i2}, respectively. ADP binding to $P2Y_1$ is necessary for platelet aggregation but is not sufficient. Instead, $P2Y_1$ is responsible for ADP-induced platelet shape change, and its engagement by ADP triggers a transient aggregatory response. $P2Y_{12}$, coupled to inhibition of adenylyl cyclase, mediates the amplification of the aggregation response.[3] The thienopyridine derivatives have no effects on arachidonic acid metabolism and hence act synergistically with ASA to inhibit platelet function.

The thienopyridines are all prodrugs of similar structure that produce active metabolites that bind irreversibly to $P2Y_{12}$, inhibiting ADP-mediated aggregation for up to 10 days after withdrawal of the drug, paralleling the platelet life span.[4] Because most platelet agonists require ADP for their full activity, the thienopyridines inhibit platelet activation by all agonists except strong agonists at high concentrations.[5] Another hypothetical advantage over ASA is their inhibition of shear-induced platelet aggregation.[6]

There are three generations of thienopyridine drugs, represented by ticlopidine, clopidogrel, and prasugrel. Ticlopidine is rarely used because of potentially serious side effects including agranulocytosis, thrombocytopenia, and thrombotic thrombocytopenic purpura.[7] The non-thienopyridine $P2Y_{12}$ inhibitors, which include ticagrelor and cangrelor, are not prodrugs and serve as reversible inhibitors.

Thrombin Receptor Antagonists

Direct-Acting Agents

Thrombin, the most potent platelet agonist, activates platelets via protease activated receptor (PAR)-1 and PAR-2. Vorapaxar, a tricyclic

himbacine derivative, is a PAR-1 antagonist with a long half-life (up to 8 days) and a slow off-rate. When used in combination with ASA, vorapaxar increased the risk of major bleeding compared with placebo. On its own, vorapaxar reduced the risk of major adverse cardiovascular events in patients with peripheral artery disease compared with placebo, but was associated with a small increase in the risk of bleeding.[8] Vorapaxar is contraindicated in patients with a history of stroke, transient ischemic attack, or intracranial hemorrhage.

Indirect Agents

The COMPASS trial showed that a combination of ASA plus low dose rivaroxaban reduced the risk of major adverse cardiovascular and limb events compared with ASA or rivaroxaban alone.[9] The mechanism responsible for the synergistic effect of ASA and rivaroxaban is unclear but likely reflects the capacity of rivaroxaban to attenuate thrombin generation and to inhibit PAR-1 activation by factor Xa.[10] Although these findings suggest that any anticoagulant that reduces factor Xa generation would have antiplatelet effects, when full dose apixaban was compared with placebo on top of antiplatelet therapy in patients with acute coronary syndrome, there was excessive bleeding with apixaban and no reduction in major adverse cardiovascular events.[11] Therefore, synergism depends on using the right dose of the anticoagulant in combination with antiplatelet therapy.

Experimental Agents

Thromboxane Receptor Antagonists

Thromboxane synthesis inhibitors and thromboxane receptor antagonists were developed to circumvent the non-platelet effects of cyclooxygenase (COX) inhibitors.[12] Development was halted when clinical trials revealed no advantages over ASA.

TABLE 128.2 Drug-Induced Platelet Dysfunction

Anti-Platelet Drugs

- Activation receptor antagonists
  - ADP receptor antagonists
  - $P2Y_{12}$ antagonists
  - Thienopyridines: clopidogrel, ticlopidine, prasugrel
  - Nonthienopyridines: ticagrelor, cangrelor, elinogrel
- Dual $P2Y_{12}$ and $P2Y_1$ inhibition: GLS-409
- Thrombin receptor antagonists
- Direct: vorapaxar, PZ-128, BMS-986120
- Indirect: anticoagulants (e.g., rivaroxaban)
- Thromboxane receptor antagonists: ridogrel, seratrodast, terutroban, sulotroban, etc.
  - GPI/IX/V antagonists: anfibatide
  - GP VI antagonists: trowaglerix derived peptides

Inactivation Receptor Agonists

- Prostanoid agonists: epoprostenol, iloprost, beraprost

Aggregation Inhibitors

- αIIbβ3 inhibitors
- parentral: abciximab, eptifibatide, tirofiban
- oral: sibrafiban, orbofiban, iotrafiban

Signaling Molecule Inhibitors

- COX inhibitors
  - Acetyl salicylic acid (ASA, brand name aspirin)
  - NSAIDs: ibuprofen, naproxen, indomethacin, etc.
- PDE inhibitors
  - Nonselective PDE inhibitors: pentoxifylline, caffeine, theophylline
  - PDE3 inhibitors: cilostazol, milrinone, anagrelide
  - PDE5 inhibitors: dipyridamole, sildenafil
- STK inhibitors: BI1002494
- 12-Lipoxygenase inhibitors: ML-355
- Classes of drugs that inhibit platelets
  - Cardiovascular agents
  - Calcium channel blockers: nifedipine, diltiazem, verapamil
  - β-Blockers: propranolol
  - Vasodilators: nitrates, nitroprusside
  - Diuretics: furosemide
  - Angiotensin II receptor antagonist: losartan, valsartan, and olmesartan
  - Antibiotics: β-lactams, amphotericin, hydroxychloroquine, nitrofurantoin
  - Antifungal drugs: miconazole, amphotericin B
  - Psychiatric drugs: TCAs, fluoxetine, chlorpromazine, promethazine, trifluoperazine
  - Oncologic drugs: mithramycin, daunorubicin, BCNU, asparaginase, vincristine, dasatinib, ibritunib
  - Anesthetics: dibucaine, procaine, halothane, sevoflurane, propofol
  - Plasma expanders: dextran, hydroxyl ethyl starch
- Heparins and thrombolytic agents
  - Miscellaneous: clofibrate, statins, cocaine, ketanserin, radiographic contrast agents, antihistamines, immunosuppressive drugs

ADP, Adenosine diphosphate; *BCNU*, carmustine; *COX*, cyclooxygenase; *NSAID*, nonsteroidal antiinflammatory drug; *PDE*, phosphodiesterase; *TCA*, tricyclic antidepressant.

GPVI Antagonists

Genetic deficiency of glycoprotein (GP) VI, a collagen receptor on platelet, is associated with a mild bleeding diathesis. GPVI antagonists include revacept, a fusion protein containing the extracellular domain of GPVI linked to an Fc fragment, antibodies against GPVI and peptide fragments of the *Tropidolaemus wagleri venom trowaglerix*.[13]

GP I/IX/V Antagonists

The GP I/IX/V complex serves as the primary platelet receptor for von Willebrand factor (vWF). Caplacizumab, which binds vWF and blocks its interaction with the receptor, is approved for the treatment of thrombotic thrombocytopenic purpura (see Chapter 132). Other agents that target the same interaction include ARC1779, an aptamer that binds vWF, and anfibatide, which binds GPIb.[13]

Activation Receptor Agonists

Adenyl Cyclase Stimulators or Prostacyclin Analogues

Epoprostenol (the synthetic salt of prostacyclin), prostacyclin (iloprost), and an orally active stable analogue (beraprost) are prostacyclin-like agents that are used for the treatment of pulmonary arterial hypertension and peripheral artery disease.[14] Despite the potent inhibition of platelet aggregation induced by prostacyclin in vitro, it has little or no effect on the bleeding time.

Aggregation Inhibitors

Parenteral $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) Inhibitors

The final common step in platelet aggregation is activation of the major platelet integrin $\alpha_{IIb}\beta_3$ to a ligand-competent form, which binds multivalent ligands such as fibrinogen or vWF, thereby cross-linking platelets into aggregates. Conventional antiplatelet agents such as ASA and clopidogrel each inhibit only one pathway leading to platelet aggregation, ASA preventing thromboxane production, and clopidogrel blocking the major ADP receptor. Dual therapy with ASA and clopidogrel improves the clinical benefit of antiplatelet therapy, but aggregation is still able to proceed through the action of other agonists such as thrombin. Because $\alpha_{IIb}\beta_3$ engagement is required for aggregation through all pathways, blocking this receptor inhibits platelet aggregation more effectively.

Inhibitors of $\alpha_{IIb}\beta_3$ work selectively and competitively to inhibit platelet aggregation.[15,16] These agents are intended to produce a transient effect akin to the defect in Glanzmann thrombasthenia, but there are important differences between the drug effect and the disease.

Although these agents share many similarities in their antithrombotic properties, they also have several clinically important pharmacokinetic and off-target effect differences. Three drugs are available: eptifibatide, tirofiban, and abciximab.

Abciximab

The first $\alpha_{IIb}\beta_3$ inhibitor approved for clinical use, abciximab (ReoPro), is a human-murine chimeric Fab fragment of a monoclonal antibody that targets the β_3 subunit of $\alpha_{IIb}\beta_3$ and therefore also reacts with another integrin that shares the β_3 subunit, $\alpha_V\beta_3$. Although $\alpha_{IIb}\beta_3$ expression is restricted to megakaryocytes and platelets, $\alpha_V\beta_3$ is expressed on platelets; at low levels; and in cells of the vascular wall, including endothelial cells and fibroblasts.[17] In addition to its antithrombotic properties, abciximab may also reduce infarct size, prevent stent thrombosis, and modulate inflammatory responses by virtue of β_3 subunit inhibition in other tissues.[15]

Abciximab administered intravenously as a standard 0.25 mg/kg bolus blocks approximately 80% of surface $\alpha_{IIb}\beta_3$ and inhibits platelet aggregation to a similar extent, although the extent of inhibition is variable.[18] This level of blockade increases the bleeding time only mildly. The bleeding time only becomes markedly prolonged when receptor blockade exceeds 90%. After the bolus dose, abciximab is infused at a dose of 0.125 μg/kg/min for 12 hours. Several trials have established this as a clinically effective regimen.[19] Plasma levels of free abciximab drop rapidly after its administration, with an initial half-life of approximately 30 minutes. Most of the drug is bound to platelets. This explains why patients with thrombocytosis may require larger weight-adjusted doses of abciximab to attain a therapeutic antiplatelet effect[19] and why patients with lower platelet counts treated with the usual dose of abciximab display more profound platelet inhibition. Abciximab is not excreted in the urine and is probably metabolized by the reticuloendothelial system when platelets carrying bound abciximab are cleared from the circulation. The dose of abciximab does not need adjustment in patients with renal impairment. Although a daily platelet turnover rate of 10% would predict that no abciximab would be detected in blood after 10 days of its administration, platelet-bound abciximab has been observed up to 3 weeks after its initial administration, suggesting platelet-to-platelet redistribution of the drug or release of new platelets from megakaryocytes that had previously bound the drug.[18] Because of the low plasma levels of unbound abciximab, the drug's inhibitory effect can be rapidly reversed by platelet transfusion, and hemostasis should be normal when the concentration of infused platelets exceeds 50,000/μL, as it is in normal individuals. However, because of the ability of abciximab to redistribute to the newly transfused platelets, the platelet-bound abciximab may produce a gradual inhibitory effect on the infused platelets;[18] in patients with severe or refractory bleeding, it may be necessary to infuse a very large dose of platelets, sufficient to leave 50% of $\alpha_{IIb}\beta_3$ receptors free, a number shown to be sufficient for normal hemostasis in studies of Glanzmann thrombasthenia heterozygotes. Without platelet transfusion, platelet aggregation generally returns to baseline levels within 12 to 24 hours after discontinuing abciximab.

Eptifibatide

Eptifibatide (Integrilin) is a cyclic heptapeptide based on the Lys-Gly-Asp (KGD) sequence found in barbourin, a platelet-inhibitory disintegrin from the venom of the Southeastern Pigmy rattlesnake, *Sistrurus miliarius barbourin*.[20] Eptifibatide differs pharmacokinetically from abciximab in several important ways.[21] For example, unlike abciximab, intravenous eptifibatide infusion produces high levels of unbound drug because of its lower affinity for the receptor. Platelet transfusion, therefore, is not a good method for acutely reversing the antiplatelet effect of eptifibatide because the newly transfused platelets are rapidly inhibited. However, its short plasma half-life (≈2.5 hours) allows for rapid clearance of eptifibatide and the reversal of its antiplatelet effect when administration is discontinued. Platelet aggregation returns to normal in approximately 4 hours, with the bleeding time normalizing within 1 hour.[21]

Tirofiban

Tirofiban (Aggrastat) is a peptidomimetic agent based on the Arg-Gly-Asp (RGD) sequence, with a pharmacokinetic profile similar to that of eptifibatide; neither cross-reacts with $\alpha_V\beta_3$.[22] As with eptifibatide, the maximum antiplatelet effect is seen at concentrations that leave a high concentration of unbound drug in the plasma. Thus, platelet transfusions are not often effective for reversal of the antiplatelet effect of tirofiban. However, its half-life is even shorter than that of eptifibatide (≈2 hours), and its antiplatelet effect diminishes rapidly after discontinuation of the infusion.

The major adverse effects of $\alpha_{IIb}\beta_3$ inhibitors are thrombocytopenia and bleeding complications. Up to 5% of patients receiving abciximab experience mild thrombocytopenia (<100,000/μL), and

1% develop profound thrombocytopenia (<20,000/μL).[23,24] The incidence of severe thrombocytopenia is lower with tirofiban and eptifibatide, being approximately 0.2%.[24,25] A decrease in the platelet count is appreciable within the first hours after administration. It is therefore essential that a platelet count be obtained 2 to 4 hours after initiating treatment. Most patients with severe thrombocytopenia respond well to platelet transfusions and their platelet counts usually recover within 5 days, although they may take more than 1 week to do so.

Bleeding complications with $\alpha_{IIb}\beta_3$ inhibitors are quite common, especially after femoral artery catheterization. Rates of major bleeding vary between 0.7% and 5.2% in different randomized controlled studies.[25,26] Intracranial bleeding is very rare (0.09%).[25] The risk of bleeding increases in patients older than 65 years of age; in patients weighing less than 50 kg; in patients taking anticoagulant, antiplatelet, or thrombolytic therapies; and in patients with inherited or acquired bleeding disorders such as hemophilia and uremia, respectively.[25,26]

Oral $\alpha_{IIb}\beta_3$ Inhibitors

Although several oral αIIbβ3 inhibitors were developed, they failed to prevent major adverse cardiovascular events and some were associated with increased mortality that was not related to bleeding.[27] A plausible but unproven explanation for the increased mortality is that these agents produce a prothrombotic state because they block platelet aggregation but not platelet activation, and the activated platelets can then promote thrombin generation.

Signaling Molecule Inhibitors

Acetyl Salicylic Acid (ASA, Brand Names Including Aspirin)

ASA has been in routine use worldwide for more than 100 years and is still the most common agent associated with platelet dysfunction.[28] The antipyretic and analgesic effect of willow bark was first recorded by Galen. In 1826 and 1828 Leroux and Buchner isolated a compound from willow bark that they called salicin (from *salix* = willow in Latin). In 1897, Felix Hoffman from the Bayer Company, inspired by his father's severe arthritis and the untoward side effects of salicylic acid, discovered a method to convert salicylic acid, the active compound in willow bark, to a compound with less gastrointestinal (GI) toxicity, acetyl salicylic acid.[29] ASA was widely used for rheumatic fever in the 1940s. In the 1950s, case reports and uncontrolled studies were published suggesting that ASA could prevent myocardial infarction and stroke.[30,31] In the 1960s, the effect of ASA on platelet activation was revealed.[30] The clinical importance of the antithrombotic effect of ASA was clearly demonstrated in a study of 22,071 physicians who received either 325 mg of ASA or placebo every other day over the course of 5 years.[32] Those receiving ASA had a 44% decreased incidence of myocardial infarction. In a large meta-analysis, it was shown that ASA reduced death from vascular events by 15% and nonfatal vascular events by 30%.[32] The primary mechanism by which ASA impairs hemostasis is through irreversible acetylation of the enzyme cyclooxygenase-1 (COX-1), an early enzyme in the synthetic pathway that produces the potent platelet agonist, thromboxane A_2 (TXA_2). Because platelets have a limited capacity to synthesize new proteins, a single low dose of ASA (30 to 100 mg)[33] or as little as 10 mg taken daily for 1 week can completely inhibit TXA_2 production and therefore impair the function of a cohort of platelets for their circulating life span.[34] ASA also acetylates the isoform of COX mostly present in endothelial cells, COX-2; COX-2 acetylation blocks the synthesis of prostacyclin, a strong inhibitor of platelet activation.[35] However, COX-2 is less sensitive than COX-1 to inhibition by ASA,[28] and endothelial cells, unlike platelets, are able to synthesize new COX-2.[36]

Platelets exposed to ASA either in vivo or in vitro predictably demonstrate impaired aggregation in response to epinephrine, ADP, arachidonic acid, and low concentrations of collagen and thrombin,[37] a result of defective TXA_2 production. These agonists have therefore been defined as weak agonists, requiring that TXA_2 diffuse out of the platelet, bind to its receptor on the platelet membrane, and reinforce aggregation by promoting secretion from α- and dense granules. ASA-treated platelets stimulated with these agonists demonstrate only a primary, reversible wave of aggregation without granule secretion. Stronger agonists (high concentrations of thrombin and collagen) do not require TXA_2 synthesis to cause platelet secretion and irreversible aggregation, and thus most hemostatic function is maintained in ASA-treated patients.

ASA may also have COX-independent actions that may affect coagulation. At the site of microvascular injury, platelets bind to exposed collagen and coagulation is initiated by tissue factor concurrently (see Chapter 121). It was reported that low-dose ASA (30 mg/day for 7 days) decreased thrombin formation in healthy volunteers.[38] Undas et al.[39] used the same microvascular injury model and showed that ASA at 75 mg/day for 7 days decreased the velocity of prothrombin consumption by 29%, thrombin generation by 29%, and delayed both activation and maximum cleavage of factor XIII by thrombin. Interestingly, high cholesterol levels (greater than 240 mg/dL) impaired the antithrombotic effect of low-dose ASA in a microvascular injury model.[40]

In contrast to the antiplatelet effect of ASA, which appears unrelated to the dose above small threshold doses, GI mucosal toxicity is dose related.[41] The mechanism of mucosal injury appears to be distinct from the effect on hemostasis, involving ionic trapping of ASA within gut mucosal cells[42] and diminished synthesis of protective gut prostaglandins.[43,44] The inhibitory effect of even a single dose of ASA on gastric prostaglandin synthesis is prolonged, with one study showing that gastric COX activity was still 57% suppressed 72 hours after a single 325 mg dose of ASA.[45] Bleeding may originate from discrete ulcers or diffuse mucosal damage and is more common to arise from the upper GI tract. The risk of bleeding is increased even with doses of ASA as low as 10 to 30 mg/day;[46] the protective effect of resistant coatings is unproven.[47] The GI risk of ASA is increased in elderly adults (older than 65 years of age) and in those with concomitant medical conditions, such as cardiovascular disease, as well as in those taking certain other medications, such as NSAIDs.[47] ASA appears to delay the healing of gastric ulcers, possibly because it also interferes with the release of growth factors from platelets, such as endostatin and vascular endothelial growth factor.[48]

Regular use of ASA (≥75 mg) impairs primary hemostasis dose-dependently.[33] ASA treatment is associated with a small but significant increase in mucocutaneous bleeding as evidenced by easy bruising, hematemesis, melena, epistaxis, and an increased frequency of blood transfusion surrounding surgeries. Because low doses have been shown to be effective in preventing thrombosis, it is likely that the use of low doses (100 mg/day or less) maintains the antithrombotic effects of ASA but reduces the risk of bleeding.

ASA may unmask mild hereditary disorders of platelet function.[49] For example, patients with mild von Willebrand disease often have a normal bleeding time that becomes markedly increased with ASA therapy.[49] The bleeding risk associated with ASA is increased in the presence of other hemostatic defects, or if ASA is given concomitantly with anticoagulant drugs.

ASA Resistance

The response to ASA therapy varies among individuals. Every day, the human body can produce approximately 10×10^{11} platelets, and this production can increase 10-fold if needed. The life span of platelets is 8 to 10 days, and every day nearly 10% to 12% of the platelets are replaced by new platelets. The capacity of the bone marrow to produce new platelets, the ASA dosage, the ASA exposure time (single doses or regular use), the ASA formulation, and individual parameters will determine the antihemostatic effect of ASA in any particular individual.

The issue of ASA resistance is hotly debated, with reported incidence rates varying from 0% to 57%.[50–53] The presence of ASA resistance is associated with high rates of cardiovascular events.[51,53]

The most important issue in determining whether laboratory ASA resistance is real is compliance. Schwartz et al.[54] evaluated 190 patients with a history of coronary disease and receiving ASA therapy. They investigated these patients on regular ASA therapy, after withdrawal of ASA for 7 days, and after observed ingestion of 325 mg of ASA. They found that 17 patients (9%) receiving regular ASA therapy had ASA resistance as defined by defective inhibition of arachidonic acid–stimulated platelet aggregation. After being observed to take the 325 mg dose of ASA, however, all but one patient displayed inhibition of aggregation. Similar results were observed in other studies.[55] Therefore, many investigators have identified noncompliance as the predominant cause of ASA resistance, and higher doses of ASA may eliminate the resistance. Although it has been shown that ASA inhibits platelet functions in a dose-dependent manner,[56] higher ASA doses failed to reduce the risk of thrombosis in large trials.[57]

Higher ASA resistance rates are reported in elderly patients, probably owing to the fact that increased gastric pH affects ASA absorption in patients taking enteric-coated forms of ASA.[33,58] Other causes of ASA resistance may include increased platelet turnover and increased COX-1 expression in new platelets[59] and overexpression of COX-2 in macrophages and endothelial cells.[60] It has also been reported that concomitant use of some NSAIDs such as ibuprofen and naproxen may prevent COX-1 inactivation in patients receiving low-dose ASA.[61,62] Similarly, increased platelet production after hemorrhage has been cited as a cause for ASA resistance.[63] Interindividual variation in the response to ASA might also be explained by genetic variations in the genes for COX-1 and COX-2, platelet integrins α_{IIb} or β_3, the ADP receptors $P2Y_1$ and $P2Y_{12}$, the TXA_2 receptor, and some coagulation proteins.[52,64–67] However, these studies showed conflicting results and have failed to confirm that ASA therapy tailored to account for genetic variation improves clinical outcomes.

In patients treated with ASA who experience recurrent arterial thrombosis, it is important to keep in mind that arterial thrombosis is a multifactorial process and that the inhibition of one, relatively minor, pathway of platelet activation may be insufficient to prevent recurrent events.

Assessment of the inhibitory effects of ASA on platelets might be important in two clinical situations: (1) in patients with arterial thrombosis, or at high risk for arterial thrombosis, to ensure that sufficient platelet inhibition is achieved by a given ASA dose; (2) for estimating the bleeding risks in patients who need surgery or who have experienced trauma.

The antiplatelet effect of ASA can be screened by different techniques, including light-transmission aggregometry, whole-blood aggregometry, PFA-100, VerifyNow ASA, measurement of serum/plasma or urinary TXB_2 metabolites, thromboelastography, flow cytometry, or other tests (see Chapters 124 and 127).

Phosphodiesterase Inhibitors

Prostacyclin increases the levels of cAMP, whereas nitric oxide (NO) increases the levels of cyclic guanosine monophosphate (cGMP). Elevation of cAMP or cGMP inhibits many pathways involving platelet activation, including shape change, $\alpha_{IIb}\beta_3$ activation, and degranulation. Phosphodiesterases (PDEs) catalyze the degradation of cAMP and cGMP, thus preventing platelet inhibition. Eleven PDE isoforms have been described, and three are expressed in platelets: PDE2, PDE3, and PDE5.[68] Many PDE inhibitors have antiplatelet effects.

Nonselective Phosphodiesterase Inhibitors

These include the methylxanthines, caffeine (1,3,7-trimethylxanthine), theophylline (1,3-dimethylxanthine), and pentoxifylline (3,7-dimethyl-1-(5-oxohexyl)xanthine). Caffeine, at a dosage of 250 mg orally three times a day for one week, was demonstrated to reduce platelet aggregation in healthy subjects.[69]

PDE3 inhibitors include anagrelide, cilostazol, and milrinone. Although anagrelide inhibits platelet aggregation in vitro, it also inhibits megakaryocyte maturation and proliferation, and causes thrombocytopenia in humans by a mechanism that is poorly understood.[70] Anagrelide is used to treat essential thrombocythemia (ET) (see Chapter 71).[71]

Cilostazol is a cyclic nucleotide PDE inhibitor with both platelet inhibitory and vasodilatory effects; its current clinical use for peripheral artery disease in the United States was preceded by its use in Japan and other Asian countries (see Chapter 146). In addition to selectively inhibiting PDE, cilostazol also inhibits adenine nucleotide uptake, a property not shared with other PDE inhibitors that further enhances its antiplatelet activity.[72]

Milrinone inhibits platelet aggregation and shape change. The drug is used for congestive heart failure.

PDE5 Inhibitors

Dipyridamole has several biologic effects, including PDE inhibition, and targets the PDE5 isoform that degrades cGMP. It also enhances the release and prevents the breakdown of prostaglandin I_2 (prostacyclin).[68,73] Primarily used for prevention of stroke, its usefulness was demonstrated by a meta-analysis of randomized trials showing that the combination of dipyridamole (particularly the modified release form) and low-dose ASA was more effective than ASA alone in secondary prevention of vascular events after transient ischemic attack or stroke (see Chapter 144).[74] Dipyridamole has been associated with a significantly increased risk of GI bleeding when used either as a single agent or in combination with ASA.[75]

Inhibitors of PDE5 are used for the treatment of erectile dysfunction.[76] PDE5 is expressed in platelets, and its inhibition results in increased levels of platelet cGMP, an effect similar to that of nitric oxide. One study examined the activation response of platelets drawn from patients taking sildenafil (Viagra) when stimulated with either ADP or low-dose thrombin. The results showed significantly reduced activation in response to ADP in sildenafil-treated platelets, suggesting that the drug impairs selected pathways of platelet function in vivo. Several reports of sildenafil-associated bleeding have appeared, including epistaxis,[77,78] hemorrhoidal bleeding,[79] spontaneous intracranial hemorrhage,[80] and acute variceal bleeding.[81]

SYK Inhibitors

Positioned downstream to GPVI, spleen tyrosine kinases (SYK) are crucial for platelet activation. BI002494 is a selective SYK inhibitor that has antithrombotic activity in rodent thrombosis models. The potential for off-target oncogenic effects[82] will need to be eliminated before further development.

12-Lipoxygenase Inhibitors

Lipoxygenases (LOXs) catalyze the oxygenation of polyunsaturated fatty acids, which leads to the synthesis of signaling molecules. 12-LOX, which is expressed in megakaryocytes and platelets, oxidizes arachidonic acid at carbon 12. Growing evidence suggests that 12-LOX is involved in platelet activation. In a murine thrombosis model, ML355, an oral 12-LOX inhibitor, attenuated thrombus formation with a minimal increase in bleeding.[83]

OTHER DRUGS THAT ADVERSELY AFFECT PLATELET FUNCTION

Nonsteroidal Antiinflammatory Drugs

In addition to ASA, many other drugs used for their antiinflammatory and analgesic properties can impair platelet function.[84] As with

ASA, their mechanism of action appears to be through inhibition of COX-1; but in contrast to ASA, these agents only temporarily affect COX-1 function, inhibiting the enzyme only as long as the active drug circulates. Among these agents, therefore, only drugs such as piroxicam, which has a plasma half-life of more than 2 days,[85] affect platelets for more than a few hours. Like with ASA, the most sensitive indicator of impaired platelet function is the inhibition of in vitro platelet aggregation and secretion. These agents induce little or no prolongation of the bleeding time, consistent with the bleeding time being a less sensitive measure of the ASA-induced defect.[84] PFA-100 may detect the defect, manifested as a prolonged closure time with the collagen/epinephrine cartridge.[86]

Reports of bleeding correlate with the effects of these agents on platelet function, suggesting that they increase the risk for excessive bleeding less than ASA. As with ASA, they may prolong the bleeding time in patients with severe hemophilia, but in two studies, therapeutic doses of ibuprofen had no effect on the bleeding time in 19 of 20 patients with hemophilia.[87] Therefore, the clinical approach to patients taking any drug that can inhibit COX-1 should be similar, but the reversibility of the effect of NSAIDs provides an added margin of safety when these agents are used. Because of the increased bleeding risk, these drugs should be stopped before surgery. The timing for cessation of NSAIDs is based on the half-lives of the individual drug. Indomethacin, ibuprofen, ketoprofen, and diclofenac all have short half-lives (2 to 6 hours) and discontinuing these drugs 1 day before surgery is sufficient. Naproxen, sulindac, diflunisal, and celecoxib have intermediate half-lives (7 to 15 hours) and should be stopped 2 or 3 days before surgery. Nabumetone, meloxicam, and piroxicam have very long half-lives (greater than 20 hours). The American College of Chest Physicians (ACCP) guidelines recommend discontinuing these drugs 10 days before surgery.[19] Analgesics such as acetaminophen and sodium or choline salicylate do not inhibit platelet function and have no adverse effects on hemostasis.[87]

Cardiovascular Drugs

Many cardiovascular drugs affect platelet functions through a variety of mechanisms.[88] Administration of nitroglycerin, isosorbide dinitrate, or nitroprusside can decrease platelet aggregation and secretion in vitro, but their effects in vivo are likely to be minimal and inconsistently observed.[84] The mechanism of platelet inhibition appears to involve the production of nitric oxide from the drug, with concomitant increases in platelet cAMP and, more markedly, cGMP.[89] β-adrenergic receptor blockers such as propranolol, metoprolol, atenolol, and pindolol have also been shown to inhibit platelet aggregation, apparently through mechanisms independent of β-adrenergic receptor blockade.[90,91] Several of these agents have been shown to blunt platelet aggregation to ADP and collagen,[92] and to decrease platelet TXA_2 production in response to agonists.[90] Blunting of serotonin uptake by platelets and inhibition of the response to serotonin have also been demonstrated. There are numerous reports of antiplatelet effects of calcium channel blockers, such as nifedipine, verapamil, and diltiazem. Most of these studies demonstrated inhibition of the aggregation of washed platelets in the presence of high concentrations (micromolar) of the drug. This effect is mainly observed with epinephrine as the agonist, and it does not appear to be related to the inhibition of calcium ion influx. Proposed mechanisms include inhibition of epinephrine binding to α2-adrenergic receptors, inhibition of the platelet response to TXA_2, and inhibition of serotonin-induced aggregation. In therapeutic doses, the calcium channel blockers do not prolong the bleeding time. At high concentrations, quinidine can act as an antagonist of platelet α2-adrenergic receptors. In one report, a patient taking 800 mg of quinidine and 650 mg of ASA daily developed melena and generalized petechiae with a normal platelet count and a bleeding time over 35 minutes.[93] In a subsequent study in two healthy volunteers, quinidine caused a mild prolongation of the bleeding time that was apparently potentiated by ASA. Quinidine and its stereoisomer, quinine, can also impair hemostasis by inducing drug-dependent antibodies that cause thrombocytopenia (see Chapter 129).

The commonly used angiotensin receptor antagonists losartan, valsartan, and olmesartan interact with the TXA_2 receptor and inhibit thromboxane-dependent platelet adhesion and aggregation.[94] Valsartan also inhibits the expression of platelet receptors including $\alpha_{IIb}\beta_3$ and GPIb.[95]

Antibiotics

Antibiotics can also affect platelet function. Those implicated most often are the penicillins and cephalosporins, which share a β-lactam ring structure. Some of these drugs produce predictable dose- and duration-related effects on the bleeding time.[96–98] Because the effect on the bleeding time is seen only in patients who are receiving large parenteral doses of antibiotics, this is a potential problem only for hospitalized patients. In a study of 74 hospitalized patients with a consistently prolonged bleeding time, the likely cause was penicillin in 39 patients (30 patients were receiving greater than 15,000,000 U/day of penicillin G, and 9 were receiving 6 to 8 g/day of ampicillin), and ASA or related drugs in seven patients.[98] Floxacillin (an isoxazolyl penicillin) was shown to significantly impair platelet function and cause severe bleeding when used in high doses in a patient with infective endocarditis.[99]

The structural properties that cause some, but not all, penicillins and cephalosporins to affect platelet function are unknown. The side-chain structure alters the antibacterial and pharmacologic properties of the penicillins and cephalosporins, and may also determine their effects on platelet function. It is postulated that the antibiotic associates with the platelet plasma membrane via a lipophilic mechanism where it perturbs receptor–agonist interactions or signal transduction.[100] The characteristic laboratory findings are a prolonged bleeding time and abnormal platelet aggregation studies that occur after several days of high-dose parenteral therapy.[97,98,101] These abnormalities do not usually subside until several days after the antibiotic is discontinued.

The frequency of clinically important bleeding in patients taking β-lactam antibiotics is low and is not predicted by a prolonged bleeding time; consequently, the causal relation to antibiotic treatment is unproven.[102] For each report implicating an antibiotic as a cause of hemorrhage, many more patients receive the same antibiotics in large doses without bleeding complications.[102]

Although antibiotic-induced platelet dysfunction usually is of little clinical importance, there are some exceptions to this rule. The frequency of clinically important hemorrhagic complications with moxalactam appears to be higher than with other antibiotics.[96] This drug has been demonstrated to inhibit ADP- and collagen-induced platelet aggregation in a dose-dependent fashion and to decrease TXA_2 generation,[103] which suggests that, like ASA, it acts on the thromboxane synthesis pathway. Furthermore, in contrast to most other β-lactam antibiotics, moxalactam contains a methylthiotetrazole-leaving group that has been implicated in the inhibition of the synthesis of the vitamin K–dependent coagulation factors.[104] Therefore, moxalactam-induced bleeding may be caused by the combination of deficiencies in vitamin K–dependent coagulation factors and impaired platelet function.

Nitrofurantoin, an antibiotic structurally unrelated to the β-lactam antibiotics, may mildly prolong the bleeding time and impair platelet aggregation at plasma concentrations in excess of 20 μM.[105]

Antifungal Drugs

Miconazole has been shown to inhibit platelet aggregation in rabbits;[106] but there is no evidence that the drug causes platelet dysfunction in humans. Concomitant use of miconazole and vitamin K antagonists may cause significant bleeding because miconazole is a strong inhibitor of CYP2C9 (see Chapter 143).[107]

Amphotericin B inhibits thrombin-induced platelet aggregation, serotonin uptake, and thrombin-induced serotonin release in vitro.[108] Studies have shown that platelet transfusion immediately after amphotericin B infusion caused poor platelet recovery and survival. An interval of at least 2 hours should separate platelet transfusion from amphotericin B therapy.[109]

Psychiatric Drugs

Platelets from patients taking tricyclic antidepressant drugs (imipramine, amitriptyline, nortriptyline) or phenothiazines (chlorpromazine, promethazine, trifluoperazine) can exhibit impaired in vitro aggregation and secretion responses to ADP, epinephrine, and collagen, but this effect is not associated with an increased risk for bleeding.[84] However, there are numerous reports of antiplatelet effects of the widely used selective serotonin reuptake inhibitors (SSRIs) such as paroxetine, sertraline, fluoxetine, and citalopram, which block the only means of platelet serotonin uptake for storage[110–114]; the effect of these drugs in decreasing platelet serotonin levels has been documented.[115,116] Prolonged bleeding times,[117] excessive bruising,[118] and defective platelet aggregation have all been noted in patients taking fluoxetine.[119] SSRI use increases perioperative and postoperative bleeding,[120] increases red cell transfusion rates during and after surgery,[121] and increases the risk of postpartum hemorrhage in pregnant women.[122] On the other hand, the cessation of the SSRI antidepressant drug may cause discontinuation syndrome or depression relapse. Thus, the benefit-risk profile should be considered before the cessation of an SSRI prior to elective surgery.

Additionally, the risk of GI bleeding is increased in patients taking SSRIs, particularly when they are combined with NSAIDs[123] or antiplatelet drugs.[124] A prospective population study showed that current use, but not previous use, of antidepressants, especially SSRIs was associated with a lower risk for myocardial infarction.[125] A systematic review found that patients with acute coronary syndromes with depression had a reduction in recurrent coronary events if they were on an SSRI.[126]

Oncologic Drugs

Administration of mithramycin has been associated with decreased platelet aggregation, a prolonged bleeding time, and mucocutaneous bleeding.[127] Daunorubicin and bis-chloroethyl-nitrosourea can both inhibit platelet aggregation and secretion when added to platelet-rich plasma, but these effects do not appear to be clinically important.[84] Vincristine inhibits platelet aggregation by interfering with the microtubule network.[128]

Tyrosine kinase inhibitors, which are used for the treatment of chronic myeloid leukemia, can cause thrombocytopenia and/or platelet dysfunction (see Chapter 69). Dasatinib and imatinib both have been demonstrated to impair platelet aggregation.[129] Dasatinib, which is specific for Src family kinase, may cause clinically relevant bleeding because of platelet dysfunction.[130]

Ibritunib is an orally administered Btk (Bruton type) kinase inhibitor used for the treatment of B-cell malignancies. It also inhibits signaling downstream of platelet GPVI (Tec [tyrosine kinases with a pleckstrin homology domain] and Src family kinases) and affects platelet adhesion to vWF under arterial flow, increasing the risk for bleeding. Acalabrutinib, a more selective Btk inhibitor, does not inhibit Src family kinases and was not associated with major bleeding in Phase II trials, suggesting that bleeding observed with ibrutinib may reflect off-target inhibition of Src family kinases. Importantly, vWF or FVIII overcame the inhibitory effect of ibrutinib on thrombin generation.[131,132]

Anesthetics

Although some local and general anesthetic agents have been shown to inhibit platelet function in vitro, this effect is generally produced at high drug concentrations.[133,134] Sevoflurane suppresses formation of TXA_2; propofol and nitrous oxide inhibit calcium mobilization.[133] Procaine inhibits calcium and P-selectin release from platelet storage pools.[135] Dibucaine is a calpain activator, induces platelet apoptosis, and inhibits platelet functions.[136] At usual doses, halothane reversibly inhibits platelet aggregation.[137]

Plasma Expanders

Dextrans are partially hydrolyzed branched polymers of glucose. Of the two preparations in clinical use, dextran 70 has an average molecular mass of 70 to 75 kDa and dextran 40 has an average molecular mass of 40 kDa. Both preparations are effective plasma expanders and can affect platelet function, but the high-molecular-weight molecules have a greater effect on hemostasis.[138] Dextran infusion also impairs platelet aggregation and platelet procoagulant activity, and can cause a modest reduction in plasma vWF concentration. However, dextran has no effect on platelet function when added directly to platelet-rich plasma in vitro.[139] Because of its effects on platelet function, dextran was explored as an antithrombotic agent, but it is no longer used for this purpose.

Hydroxyethyl starch, known as hetastarch, is a synthetic glucose polymer with an average molecular weight of 450,000 (range: 10,000 to 1,000,000) that is also used for plasma expansion. Hetastarch use has been associated with abnormal platelet function (albeit inconsistently), a problem more evident with the higher-molecular-weight forms.[140] Like dextran, it can prolong the bleeding time, particularly if administered at doses higher than 20 mL/kg in a 6% solution, and predisposes to bleeding if administered simultaneously with heparin or in the presence of a preexisting hemostatic defect.[141]

Heparins and Thrombolytic Agents

Although heparin is best known for its anticoagulant effect and its association with HIT and thrombosis (see Chapters 131 and 143), it also has the potential to affect platelet function. Heparin can bind to the platelet surface,[142] induce platelet aggregation and secretion,[143] and impair vWF-dependent platelet function.[144] Whether these phenomena contribute to heparin-induced bleeding is unknown. The prolonged bleeding time is probably the result of inhibition of thrombin generation, analogous to the slight but significant increase in bleeding times seen in patients with hemophilia.[143]

Paradoxically, heparin is also capable of inducing the association of vWF with the GPIb complex.[145] Whether this is restricted to certain individuals or occurs only at certain heparin concentrations is unclear, but it raises the possibility that this mechanism may contribute to heparin-induced thrombosis.

Bleeding during therapy with plasminogen activators is predominantly caused by fibrin degradation, hypofibrinogenemia, and increased levels of fibrin(ogen) degradation products, usually in the setting of structural lesions. At pharmacologic concentrations, streptokinase, urokinase, and tissue plasminogen activator (t-PA) may also impair platelet function through several potential mechanisms, all related to excessive production of plasmin.[146] First, high levels of fibrin(ogen) degradation products and low levels of fibrinogen can impair platelet aggregation. Second, the binding of plasminogen to the platelet surface may facilitate its conversion to plasmin.[147] Plasmin can degrade GPIbα (thereby impairing the interaction of the platelet with vWF[148]) and fibrinogen (thereby dispersing platelet aggregates).[149] Third, plasmin can inhibit platelet aggregation by blocking the release of arachidonic acid from platelet membranes, thereby limiting TXA_2 production.[150] The clinical importance of these observations is unknown.

In addition to decreasing platelet function, plasmin has been shown to directly activate platelets,[151–154] an effect that may contribute to vessel reocclusion after t-PA treatment for myocardial infarction.[155] Platelet activation is the result of plasmin-mediated cleavage of protease-activated receptors, particularly PAR4.[156]

Miscellaneous Drugs

The statins, which inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase, are widely used in patients with dyslipidemia.[157] These agents reduce the risk of cardiovascular events through a variety of mechanisms, including reducing the risk of atherothrombosis. Among its antithrombotic effects are decreases in platelet reactivity, partly brought about by its beneficial effects on endothelial cells, with increased production of nitric oxide and prostacyclin, and by direct effects on platelets.[158] Some of the effects of statins on platelets may be dose-related. Membrane cholesterol content, which is lowered by the statins, has been correlated with platelet reactivity,[159,160] with studies demonstrating that the content of cholesterol in platelet membranes correlates with localization of important adhesive and agonist receptors within membrane microdomains known as lipid rafts.[161,162] In addition to lowering plasma and membrane cholesterol levels, statins also reduce the activity of stimulatory signaling pathways involving the small guanyl triphosphate (GTP)–binding proteins Ras, Rho, and Rac, which require posttranslational prenylation to be targeted to cell membranes. Statins inhibit protein prenylation.[163] No bleeding complications have been associated with statin use, but a substudy of the Platelet Receptor in Ischemic Syndrome Management (PRISM) trial showed that their sudden withdrawal in the setting of acute coronary syndrome was associated with an increased cardiac risk compared with the risk in patients who continued to receive statins (relative risk: 2.93) or never received statins.[164] This increase in adverse cardiac events was partially attributed to increased platelet reactivity. A recent meta-analysis found no correlation between statin therapy and increased intracranial hemorrhage.[165]

Clofibrate, another lipid-lowering drug, diminishes platelet responsiveness to ADP, collagen, and epinephrine when given to patients with type II hyperbetalipoproteinemia, and can diminish the responsiveness of normal platelets to ADP and epinephrine in vitro.[84]

Cocaine accounts for many drug-related visits to emergency departments in the United States. Its use is associated with a large increase in the incidence of myocardial infarction in individuals who are otherwise at low risk, and it has been hypothesized that cocaine-induced platelet aggregation is a major contributor to this risk.[166] In vitro, however, cocaine inhibits platelet aggregation in response to several agonists and dissociates preformed aggregates.[167] Another important prothrombotic mechanism associated with cocaine use is the ability of cocaine and its long-acting metabolites to induce the release of vWF from endothelial cells.[168]

Ketanserin, which has been studied for its potential to prevent atherosclerotic complications, decreases platelet aggregation in response to serotonin. Antihistamines, some radiographic contrast agents, and immunosuppressive drugs can also impair platelet aggregation. The mechanisms responsible for these effects are unknown.

Foods and Food Additives

Certain foods and food additives can have important effects on platelet function, particularly when consumed in large quantities. In a classic study published in 1979, Dyerberg and Bang[169] reported that Greenland Inuit on traditional diets had markedly prolonged bleeding times compared with gender- and age-matched Danish control subjects (mean: 8.1 minutes vs. 4.8 minutes, respectively), and they correlated this finding with an impaired secondary wave of platelet aggregation to ADP and collagen, and high plasma levels of ω-3 fatty acids. The proposed mechanisms by which ω-3 fatty acids (eicosapentaenoic acid, C20:5ω-3; and docosahexaenoic acid, C22:6ω-3) interfere with platelet function is through competition with arachidonic acid for the 2-acyl position of membrane phospholipids or access to COX-1.[170,171] ω-3 Fatty acids not only reduce TXA_2 synthesis in response to platelet agonist stimulation by competing with the substrate arachidonic acid, but also by producing inhibitory eicosanoids. The latter mechanism was substantiated in the original study of an Inuit population by the demonstration that administration of ASA decreased the bleeding time in all subjects tested but not to normal levels.[169] Additionally, ω-3 fatty acids may increase the production of antiaggregatory prostaglandins by cells in the vessel wall.[169] In a general population age over 50, supplementation of ω-3 fatty acid did not reduce major adverse cardiac events.[172] However, in patients with hyperlipidemia, icosapent ethyl, a highly purified eicosapentaenoic acid ethyl ester, reduced major cardiovascular events by 22% (22.0% to 17.2%)[173] most likely by reducing plaque volume.[174] Icosapent ethyl was associated with a small increase in serious bleeding (2.1% to 2.7%).[173]

Ethanol, one of the most commonly and excessively ingested substances in the world, acts synergistically with ASA to prolong the bleeding time (see Chapter 126).[175] In addition, ethanol acts cooperatively with agents that block binding of fibrinogen to $\alpha_{IIb}\beta_3$ to further reduce platelet aggregation in response to several agonists, an effect not solely the result of reduced TXA_2 generation.[176] Ethanol can also impair collagen-induced platelet aggregation, secretion, arachidonate mobilization, and TXA_2 formation, but it did not inhibit platelet adhesion to deendothelialized rabbit aortae.[177]

Other food components or additives can also affect platelet function and increase the risk of minor bleeding. Easy bruising after eating Chinese food has been attributed to a platelet inhibitory effect of black tree fungus.[178] A component of onion extract can inhibit platelet arachidonic acid metabolism.[179] Ajoene, a component of garlic, is an inhibitor of fibrinogen binding to platelets and platelet aggregation.[180] Extracts from frequently consumed spices—cumin, turmeric, and clove—can decrease platelet thromboxane production and inhibit platelet aggregation.[181] Bromelain, an extract from pineapple, can inhibit ADP-induced platelet aggregation, and prolong both the PT and aPTT.[182] Parsley (*Petroselinum crispum*) may inhibit ADP-induced platelet aggregation.[183]

It can be concluded that platelets are sensitive to a variety of therapeutic and dietary compounds, the extent of inhibition primarily depending on the dose of the inhibitory agent.[84] However, an increased risk for clinically important bleeding has been demonstrated only for ASA and agents specifically designed to inhibit platelet function. Reports of increased bleeding with all other agents must be viewed with caution. Despite this qualification, it is prudent for clinicians to have a thorough understanding of the antiplatelet effects of prescribed drugs and to always consider the potential impacts of drug- or diet-induced platelet dysfunction, particularly in patients with coexisting hemostatic defects or those consuming large amounts of these agents.

Scurvy

Vitamin C deficiency results in defective collagen synthesis and abnormal bleeding from fragile capillaries. Platelet aggregation defects in patients with scurvy normalize after vitamin C supplementation.[184]

CLONAL DISORDERS

Hematological Clonal Disorders

Myeloproliferative Neoplasms

Myeloproliferative neoplasms (MPNs; see Chapters 69–73) are clonal disorders arising from hematopoietic stem cells affected by somatic mutations that cause abnormal production of mature myeloid cells. Philadelphia chromosome-negative MPNs, which include polycythemia vera (PV), ET, and primary myelofibrosis, are the most common MPNs. These disorders are characterized by varying degrees of leukocytosis or thrombocytosis; patients with PV usually have a markedly elevated hematocrit. Particularly in PV and ET, thrombosis or bleeding accounts for a high percentage of the associated morbidity, with thrombosis being the most common.

Bleeding in patients with MPN is primarily mucocutaneous. The bleeding time is prolonged in a small percentage of patients with

MPNs, but bleeding complications can occur even in patients with normal bleeding times. Routine plasma coagulation tests, such as the PT and aPTT, may be falsely prolonged if the red blood cell mass is increased. Because the plasma volume in these patients is reduced, it is important to adjust the citrate concentration in the tubes used to collect the blood for coagulation testing.

The mechanisms of bleeding are multifactorial in patients with MPN. Some bleeding episodes can in part be attributed to thrombosis, such as variceal bleeding resulting from thrombosis-induced portal hypertension.[185] Acquired platelet abnormalities, acquired coagulation factor (especially factor V) and vWF deficiencies,[186] antiplatelet drug usage, and drugs used for the clonal disease (such as anagrelide) may cause bleeding problems.

The platelets of patients with MPNs can show various morphologic abnormalities, including variations in size and shape, as well as reduced numbers of secretory granules. Platelet survival can be decreased in ET. The most common platelet abnormality is decreased aggregation and secretion in response to agonists, particularly epinephrine, ADP, and collagen.[187] These abnormalities are not simply the result of the high platelet count, because patients with reactive thrombocytosis have functionally normal platelets.[188] In what may appear to be a paradox, some patients demonstrate spontaneous in vitro platelet aggregation in platelet-rich plasma. Decreased platelet aggregation or secretion and decreased procoagulant activity may be caused by (1) agonist-induced release of arachidonic acid from membrane phospholipids; (2) conversion of arachidonic acid to prostaglandin endoperoxides or lipoxygenase products; (3) platelet responsiveness to TXA_2; (4) dense-granule or αα-granule contents; or (5) α2-adrenergic receptors. Some of the described abnormalities may also be a consequence of platelet activation in vivo or ex vivo during platelet preparation.

Specific platelet membrane abnormalities have also been reported, including deficiencies of GPIb and GPIX, causing an acquired form of the Bernard-Soulier syndrome (see Chapter 124)[189]; deficiencies of receptors for prostaglandin D_2[190]; c-MPL receptors[191]; and an increased number of Fc receptors.[192] Because MPNs are clonal in origin, the abnormal platelets can arise from a clone of abnormal megakaryocytes.[193] Alternatively, the findings may be the result of platelet hyperreactivity and previous activation.[194,195] It is important to emphasize several features about the platelet function defects reported in MPNs. First, no defect has consistently predicted the risk for bleeding or thrombosis. Second, no defect is unique to, and therefore predictive of, a particular MPN. Third, the relative frequency of the different defects varies widely. Therefore, the clinical importance of the abnormalities of platelet function in MPNs is unknown.

Acquired von Willebrand syndrome (see Chapter 133) can cause mucocutaneous bleeding or complicate surgical interventions in nonbleeding patients. In acquired von Willebrand syndrome, the largest multimers of vWF are absent, possibly as a consequence of their adsorption to binding sites on the elevated numbers of platelets,[196–200] or because of disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13) proteolysis of the large multimers.[201] In a prospective study of MPN patients, the incidence of acquired von Willebrand syndrome was 11%.[202] Although increased adsorption of plasma vWF multimers by platelets is the cause of the syndrome and decreased vWF:ristocetin cofactor activity/Ag or vWF:collagen binding/Ag ratio was found in patients with extreme thrombocytosis,[200] acquired von Willebrand syndrome has also been described in patients with platelet counts between 120 and $135 \times 10^9/\mu L$.[202]

Several intrinsic platelet function defects result, at least in part, from an increased sensitivity of the platelets to activation, a potential consequence of the JAK2 gain-of-function mutation. For example, a study demonstrated an increased risk of thrombosis in patients with chronic MPN when the mutant kinase was detected in platelets or in platelets and granulocytes.[193] Likewise, the JAK2 mutation in platelets correlated with increased platelet expression of tissue factor and P-selectin, decreased expression of CD41 and CD42b, and increased quantities of platelet–neutrophil aggregates, all indicators of a hyperreactive platelet phenotype.[194] Panova-Noeva et al.[195] evaluated the platelets from 140 patients with MPN (80 ET, 60 PV) for global procoagulant potential by measuring thrombin generation and expression of tissue factor and P-selectin on the platelet surface. They found that patients with the JAK2 V617F mutation had the highest values for thrombin generation and platelet tissue factor and P-selectin expression. These findings correlated with JAK2 V617F allele burden.[195]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH; see Chapter 32) is another clonal disorder that involves all blood cells. The hematopoietic stems cells and their progeny are defective in the synthesis of the glycosylphosphatidylinositol attachments required for the plasma membrane expression of some membrane proteins, leading to a defect in all glycosylphosphatidylinositol-linked proteins on blood cells,[203] including platelets.[204]

Thrombosis is a leading cause of mortality in PNH, affecting at least half of these patients. The platelet function abnormalities described in PNH range from hypersensitivity to agonists to dysfunction.[205] One study showed platelets to be hypersensitive to epinephrine, ADP, and collagen, as judged by their abilities to aggregate and to release ^{14}C serotonin.[206] The total release of nucleotides was also markedly increased over normal with all aggregating agents. By contrast, another study examining platelets from PNH patients showed them to be profoundly hyporeactive, as measured by defective clot formation, adhesion, and aggregation.[207] This finding was interpreted as being a consequence of chronic overstimulation of the platelets while they circulate. Platelet activation and increased platelet microparticle formation have also been demonstrated in PNH patients.[205,206,208]

Paraproteinemias

Although thrombotic complications can occur in patients with paraproteinemias because of hyperviscosity, bleeding complications also are seen. Platelet dysfunction is observed in approximately one-third of patients with immunoglobulin (Ig)A myeloma or Waldenström macroglobulinemia, in 15% of patients with IgG myeloma, and occasionally in patients with benign monoclonal gammopathy (see Chapters 90–92).[209,210] Additional hemostatic problems in these patients can be caused by the hyperviscosity syndrome,[211,212] a heparin-like coagulation inhibitor,[213] acquired von Willebrand syndrome,[200] or complications of amyloidosis (e.g., acquired factor X deficiency[214] or enhanced fibrinolysis).[215] Patients may have markedly abnormal results on laboratory tests (e.g., a prolonged thrombin time) with no evidence of clinical bleeding.[209]

Abnormalities of platelet function correlate with the concentration of the plasma paraprotein. Myeloma proteins can inhibit all platelet functions (aggregation, secretion, procoagulant activity, and clot retraction), and normal platelets can acquire these defects when incubated with the purified monoclonal immunoglobulin.[216,217] In some cases, specific interactions of the monoclonal protein have been described. One IgA myeloma protein inhibited the ability of a suspension of aortic connective tissue to aggregate normal platelets.[218] The bleeding time and bleeding symptoms of the patient from whom this paraprotein was isolated were corrected when the IgA myeloma protein was removed by plasmapheresis. One patient had a fatal hemorrhage from an IgG1κ paraprotein that bound GPIIIa (β_3 integrin) and inhibited platelet aggregation.[219] A number of reports have described acquired von Willebrand disease in patients with myeloma, benign monoclonal gammopathy, or chronic lymphocytic leukemia.[220] In some patients, the plasma concentration of vWF was decreased; in others, the larger multimers were deficient. The myeloma protein can either accelerate vWF clearance from plasma or interfere with its binding to platelet GPIb.

Easy bruising, epistaxis, periorbital purpura (in patients with amyloidosis), and GI hemorrhage are the most common bleeding symptoms associated with the paraproteinemias. Because bleeding appears to be related to high plasma paraprotein concentrations,[221] chemotherapy for the underlying plasma cell neoplasm should be given to effect a longer lasting reduction of the paraprotein. In emergency situations, plasmapheresis should be performed expeditiously; the effectiveness of this therapy can be evaluated by improvement of bleeding. Intravenous immunoglobulin (IVIG) infusions are effective in controlling bleeding in patients with plasma cell dyscrasias and acquired von Willebrand disease. IVIG can produce a clinical and laboratory response in 12 to 72 hours, and the effect usually persists for 1 to 3 weeks. In patients with severe bleeding, IVIG can be combined with plasmapheresis, desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP), and infusions of vWF concentrate or factor VIIa.[200,202,210,220]

Leukemias and Myelodysplastic Syndromes

Bleeding in patients with the leukemias and myelodysplastic syndromes (MDS) is almost always caused by thrombocytopenia, but abnormalities of platelet function have also been described. In acute myeloid leukemia and its variants, platelets may be larger than normal, abnormally shaped, and vary in their granule numbers (see Chapter 61). Abnormal platelet structure and function have been described, especially in association with acute megakaryoblastic leukemia (FAB M7),[222–224] with one study describing three patients with decreased aggregation to collagen, ADP, epinephrine, and the thromboxane analogue U46619, along with a decreased platelet serotonin content.[222] Platelet abnormalities can also be found in the MDS, with defective aggregation and glass bead retention most often associated with hypolobulated megakaryocytes and the 5q− syndrome.[224,225] Abnormal platelet function has also been described in association with B-cell malignancies, such as hairy cell leukemia, which can persist after splenectomy,[226] and with chronic lymphocytic leukemia,[227] in which the platelets exhibit reduced responses to GPVI agonists such as collagen and convulxin.

Also, acquired platelet GP defects have been reported in hematological malignancies, including acquired Glanzmann thrombasthenia in a patient with Hodgkin lymphoma[228] and acquired Bernard-Soulier syndrome in a child with MDS.[229]

Solid Tumors

Bleeding complications in patients with cancer are related to decreased platelet production caused by bone marrow infiltration, the myelosuppressive effects of chemotherapy and radiotherapy, sepsis, disseminated intravascular coagulation, microangiopathic hemolytic anemia, drug-induced thrombocytopenia, immune thrombocytopenia, or hypersplenism. Although several defects of platelet functions have been described in cancer patients, none are specific.[230]

SYSTEMIC METABOLIC DISORDERS

End-Stage Renal Disease

The pathogenesis of the hemorrhagic diathesis in patients with end-stage renal disease (ESRD) is complex (see Chapter 150). Factors such as platelet function abnormalities caused by uremic toxins, anemia, hemodialysis procedures (both the artificial circulation and the use of anticoagulation), and decreased drug clearance may impair hemostasis.

In ESRD patients both platelet hypofunction and platelet hyperreactivity can occur.[231]

Deficiencies in the number of GPIb complexes in uremic platelets have been reported, the number inversely correlating with the creatinine level.[232] Consistent with this finding, another study demonstrated that defective ristocetin-induced platelet aggregation of uremic platelet-rich plasma was not corrected by resuspending the platelets in normal platelet-poor plasma. Likewise, uremic platelets suspended in normal plasma were defective in their adhesion to deendothelialized rabbit vessels at high shear, a test of the competency of the interaction between GPIb and vWF.[233] Conversely, the same study demonstrated that plasma factors also influence platelet function by showing that normal platelets suspended in uremic plasma acquired an adhesion defect possibly related to an abnormal interaction of vWF with the subendothelium. This led to the suggestion that vWF may be abnormal in uremia. Two studies have demonstrated normal-to-elevated vWF antigen and activity (measured as ristocetin cofactor activity) in uremic patients but decreased levels of the largest, most hemostatically active multimers,[234,235] reflected in one study as a decreased ratio of activity to antigen level compared with the vWF from normal subjects.[234] Taken together, the various studies consistently indicate that the first step of platelet adhesion at sites of vessel wall injury is abnormal, a defect that could be clinically significant if coupled with other defects of platelet function.[231]

The platelets of uremic patients frequently exhibit reduced fibrinogen binding, aggregation, and secretion in response to a wide variety of agonists. This abnormality may persist when the platelets are removed from uremic plasma, and in some studies, uremic plasma has induced these defects in normal platelets. One potential mechanism is provided by the demonstration that fibrinogen fragment levels are elevated in patients with ESRD and bind to platelet $\alpha_{IIb}\beta_3$, inhibiting platelet aggregation.[236]

Uremic platelets can also exhibit a reduction in several of the biochemical responses necessary for aggregation and secretion, including the rise in cytoplasmic calcium ion concentration, release of arachidonic acid from membrane phospholipids, conversion of arachidonic acid to TXA_2, and dense-granule and α-granule secretion. Abnormal cytoskeletal assembly and deficient tyrosine phosphorylation have also been noted in uremic platelets, abnormalities only partially corrected by dialysis.[231,237]

The accumulation of dialyzable platelet-inhibitory substances in the plasma of uremic patients has long been recognized. The ability of uremic plasma to inhibit platelet function was demonstrated in the late 1960s by Horowitz and colleagues,[238] who showed reduced ADP-induced platelet aggregation and a prolonged Stypven clotting time, a measure of platelet procoagulant activity. This activity, previously called platelet factor 3, is vital for the support of coagulation factor complex assembly on the platelet surface and requires externalization of the anionic phospholipid phosphatidylserine. One uremic substance with platelet inhibitory properties described by Horowitz and coworkers[239] was guanidinosuccinic acid, which accumulates in uremic plasma as an alternative byproduct of L-arginine metabolism,[240] a consequence of the inhibitory effect of high urea levels on enzymes of the urea cycle. Similar to L-arginine, guanidinosuccinic acid is a precursor of nitric oxide, which is produced in increased quantities in the endothelial cells and platelets of uremic patients and experimental animals.[240] Consistent with an important role for nitric oxide in uremia, infusion of the nitric oxide synthesis inhibitor monomethyl L-arginine reduced the bleeding time in uremic rats.[241] Furthermore, suppression of nitric oxide production appears to correlate with the benefit of conjugated estrogens in improving the bleeding time in uremia.[242] Increased expression of vascular prostacyclin has also been described in uremic rats, a factor that would further depress in vivo platelet function.[243]

Dialysis itself may be associated with alterations in platelet function. For example, hemodialysis can reduce the responsiveness of platelets to agonists in vitro,[244] and chronic hemodialysis and peritoneal dialysis are associated with an increase in reticulated platelets, suggesting accelerated platelet turnover.[245] Of the two forms of dialysis, hemodialysis appears to have the greatest effect on platelet function, with one study noting abnormal cytoskeletal assembly and defective tyrosine phosphorylation to thrombin stimulation in the platelets of patients on hemodialysis, parameters that returned almost to normal with the institution of ambulatory peritoneal dialysis.[237] The cause of the defect associated with hemodialysis is likely to be the chronic low-level platelet activation associated with the procedure. In particular, polymerization and depolymerization of actin, release of granule proteins and their binding to the platelet surface, and shedding of membrane proteins may render the platelets relatively refractory to activation.

Uremia and artificial surfaces during hemodialysis also affect platelet messenger RNA (mRNA) and microRNA profiles and alter protein expression.[246]

As would be expected, platelets from uremic patients may be unusually sensitive to medicines that decrease platelet function. ASA has been reported to produce a greater prolongation of the bleeding time in uremic patients than in controls, an effect that may be attributable to more than the irreversible inhibition of COX-1.[247] Similarly, β-lactam antibiotics that prolong the bleeding time can also have a greater effect in uremic patients and may increase the risk of bleeding, particularly those antibiotics cleared by the kidney.[84,248]

Anemia, which does correlate with the severity of the renal failure, is an independent cause of a prolonged bleeding time,[248–251] and the defect correlates with the severity of the anemia. The relationship of the bleeding time to hematocrit in uremic patients has been confirmed by its correction with the transfusion of red blood cells and by treatment with erythropoietin.[231,251,252]

In contrast to the studies of platelet function performed to understand the possible increased risk for bleeding in patients with chronic renal failure, the coagulation and fibrinolytic systems have been interrogated to understand the increased risk for thrombotic complications, a major cause of mortality.[253]

Uremia-related contributions to a thrombotic tendency include endothelial dysfunction, increased tissue factor (TF) expression, increased microparticle generation, increased coagulation factors (fibrinogen, FXIIa, FVIIa) and proinflammatory markers, decreased natural anticoagulant levels, and changes related to renal replacement therapy as extracorporeal thrombin generation, decreased fibrinolysis, and membrane-induced platelet activation.[231,254]

Liver Disease

The bleeding diathesis observed with fulminant or end-stage liver disease (Chapter 150) is multifactorial, with contributing causes including thrombocytopenia, anemia, deficiencies in liver-synthesized coagulation factors, and excessive fibrinolysis.[255,256] Patients with chronic liver disease and hepatic cirrhosis of various causes have been reported to have prolonged bleeding times, and these disorders are associated with other platelet function abnormalities possibly related to a decrease in GPIb.[256] Although an association between prolonged bleeding time and GI hemorrhage has been demonstrated in some studies of cirrhotic patients,[255] other studies showed that the bleeding time and platelet aggregation abnormalities correlated best with the degree of thrombocytopenia,[257] suggesting that no specific platelet function defect exists in liver disease. An ASA-like defect has been reported in patients with severe liver disease, with defective aggregation and TXA_2 production.[258] Interestingly, one study showed that platelets obtained from the portal circulation of patients with hepatocellular cancer on a background of cirrhosis showed decreased and delayed aggregation in response to collagen compared with circulating platelets.[259] In addition to portal hypertension and esophageal varices, this finding raises the possibility that localized vascular bed factors (including increased prostacyclin) may contribute to variceal bleeding.

Because patients with cirrhosis often have a complicated hemostatic picture that includes thrombocytopenia, decreased fibrinogen levels, and prolonged PT and aPTT, one might expect this to uniformly produce a severe bleeding diathesis. However, recent studies have shown that the hemostatic defects in these patients are at least partially compensated through several mechanisms. The potential to bleed because of thrombocytopenia is reduced because vWF levels are often elevated and ADAMTS13 activity is decreased,[260–262] perhaps because of decreased synthesis by hepatic stellate cells. The decreased concentrations of procoagulant factors are balanced by the decreased concentrations of anticoagulant proteins.[263] Dysfibrinogenemia produces a less severe hemostatic defect because of decreased plasminogen levels.[264,265] This balance may easily be tipped in either direction, favoring either bleeding or thrombosis.

Although patients with cirrhosis may have platelet dysfunction, it is usually not associated with serious bleeding. Bleeding in these patients cannot be predicted with routine diagnostic tests, such as the platelet count and bleeding time.[261,266]

Hypothermia

Hypothermia is defined as a core body temperature below 35°C (95°F) and is classified as mild (32°C to 35°C), moderate (28°C to 32°C), severe (20°C to 28°C), or profound (below 20°C). The most common cause of hypothermia is exposure to cold weather or immersion in cold water, but hypothermia can also be caused by dehydration, severe trauma, massive transfusion, head injury, burns, sepsis, and drugs (e.g., alcohol, sedatives, and hypnotics). Age is an important risk factor because elderly adults and newborns are particularly prone to hypothermia. Hypothermia can be intentionally induced in some cardiac operations.[267]

Mild hypothermia is usually well-tolerated, but mortality increases when the core body temperature falls below 20°C. In animals, hypothermia causes thrombocytopenia because of platelet sequestration in the spleen and liver. Hypothermia inhibits platelet aggregation in response to thrombin and thromboxane, increases platelet expression of P-selectin, and decreases expression of the GPIb-IX-V complex.[268] Both the thrombocytopenia and the functional defects are reversible, returning to normal when the body temperature normalizes.[267]

Trauma

Trauma-associated hemorrhage is a leading cause of death worldwide. Platelets are dysfunctional in critically injured patients.[269] A recent publication described the phenomenon of platelet ballooning in response to trauma. Ballooned platelets are coated in histone H4, which can activate the coagulation system, and release procoagulant microparticles that bind to leukocytes. Platelets can be induced to undergo ballooning by in vitro exposure to histone H4; an effect that was independent of the histone H4 receptors (toll-like receptors 2 and 4), suggesting that histone H4 can directly affect the platelet membrane.[270] Consistent with this concept, the proteomes of dysfunctional platelets in trauma patients exhibit 16-fold higher levels of histone H4 than normal platelets, as well as higher levels of other proteins associated with inflammation.[271]

In patients with trauma-associated intracranial hemorrhage, neither platelet transfusion nor desmopressin improved outcome in those taking ASA or clopidogrel.[272]

PLATELET DYSFUNCTION RELATED WITH EXTRACORPOREAL CIRCUITS

Extracorporeal circuits such as cardiopulmonary bypass (CPB), extracorporeal membrane oxygenation (ECMO), continuous flow left ventricular assist devices (LVADs), and total artificial heart generate high shear stress and affect blood cells, endothelial cells, and plasma proteins.

Bleeding complications can be seen in 10% to 20% of the patients undergoing CPB, and hemostatic disturbances are responsible for bleeding in nearly half of those patients.[273,274] CPB activates both the coagulation and fibrinolytic systems and causes consumption coagulopathy. Besides the surgery itself, high shear stress and exposure of the blood to artificial surfaces activates FXII and FXI directly and induces blood cells to express TF.[273,275]

Typical findings after bypass surgery include a prolonged bleeding time (longer than expected for the degree of thrombocytopenia), decreased platelet aggregation, decreased platelet agglutination in response to ristocetin, and depletion of platelet α-granule and dense granule contents.[276]

As with hemodialysis, the platelet defect caused by CPB is most likely a consequence of platelet activation and fragmentation within the extracorporeal circuit. The severity of the platelet abnormalities correlates with the duration of the bypass procedure.[274] With uncomplicated surgery, platelet function returns to normal within 24 hours; however, a much longer time may be required in some patients, and the platelet count typically does not return to normal for several days.[277]

Thrombocytopenia is caused by hemodilution and deposition of platelets on the bypass circuit and, to a lesser extent, sequestration of damaged platelets in the liver. Platelet dysfunction during bypass may be caused by reversible adhesion and aggregation of platelets on fibrinogen adsorbed from plasma onto the bypass circuit material, mechanical trauma and shear stress, cardiotomy suction, trace concentrations of circulating thrombin and ADP, complement activation, hypothermia, blood conservation devices, bypass priming solutions, and, with bubble oxygenators, exposure of platelets to the blood–air interface.[84,273] CPB consistently induces the formation of platelet fragments or membrane "microparticles," evidence that the platelet surface membrane is subjected to severe mechanical stress and activation during the procedure.[278] Thus considerable platelet activation and aggregation occur during CPB, which leads to deleterious effects from substances released from the platelets and the new adhesive molecules exposed on their surfaces, and renders the platelets relatively refractory to activation by agonists.

Another surgical cause of platelet dysfunction relates to the use of deep hypothermic circulatory arrest in some surgeries. This procedure involves cooling the vital organs to temperatures between 15°C and 22°C (59°F and 71.6°F) for reducing oxygen requirements of major organs such as the heart, brain, and kidney.[267]

In patients with mechanical circulatory support such as LVADs or ECMO, continuous exposure of blood to nonbiological surfaces creates additional hemostatic problems.[279,280] Continuously elevated shear stress both elongates and degrades vWF multimers mechanically and facilitates the cleavage of high-molecular-weight vWF multimers by ADAMTS13, causing acquired von Willebrand disease.[280] Acquired von Willebrand disease (see Chapter 133) was less severe with an axial-flow LVAD, than with a centrifugal flow LVAD.[281] Increased shear stress created by these devices also causes platelet receptor shedding. In a study evaluating patients with ECMO and continuous flow LVADs, platelet surface receptor shedding was demonstrated by elevated soluble GPVI levels in plasma, and significantly reduced expression of GPVI and GPIbα on the platelet surface.[268] However, another study reported normal levels of GPIIb, GPIX, and GPIbα on the platelet surface with LVADs, but found reduced secretion from platelet α- and dense granules in response to thrombin.[281]

INFECTIOUS DISEASES

SARS-CoV-2

Infection with SARS-CoV-2 is associated with micro- and macrovascular thrombosis (see Chapter 153). Platelets from patients infected with SARS-CoV-2 show increased response to agonists likely as a result of increased MAP kinase activation and increased thromboxane production.[282,283]

Tropical Diseases

Numerous tropical infections cause thrombocytopenia. These will not be covered. Some tropical infections inhibit platelet activation with or without causing thrombocytopenia. Although a low platelet count portends a poor prognosis in patients with dengue fever, bleeding does not correlate with the platelet count. Platelet aggregation and dense-granule release are impaired in patients with dengue fever,[284] likely reflecting platelet exhaustion. The dengue protein DENV binds to platelets and activates them.

Platelets in patients with hantavirus infection exhibit impaired activation in response to multiple agonists.[285] Others have demonstrated increased platelet activation[286] in patients with hantavirus infection. For Lassa fever, Ebola infection, and Marburg infection, bleeding does not correlate with thrombocytopenia, implying platelet dysfunction. In Lassa fever a plasma inhibitor of platelet activation was found.[287] A rhesus model of Ebola infection reported impaired platelet activation to a wide range of agonists; plasma from infected monkeys did not transmit the platelet defect to other monkeys, implying that it was inherent to the platelets.[288]

Leptospirosis can cause thrombocytopenia, but bleeding is usually mild. An exception is hemorrhagic pneumonitis, which is a common cause of death in those with leptospirosis. Platelets from patients with leptospirosis had impaired activation to ADP and thrombin receptor-activating peptide (TRAP), and this dysfunction correlated with outcome better than platelet count did.[289]

Antiplatelet Antibodies

Immunoglobulins can bind to platelets in a specific or nonspecific fashion and can disrupt platelet function. In conditions such as immune thrombocytopenic purpura (ITP) (see Chapter 129), systemic lupus erythematosus (SLE) (see Chapter 139), and platelet alloimmunization, the antibodies can trigger accelerated platelet destruction and subsequent thrombocytopenia. Surviving platelets, known as stress platelets, display enhanced function.[290] Indeed, bleeding times in ITP may be shorter than expected for the degree of thrombocytopenia. Sometimes, however, the hemorrhagic tendency is out of proportion to the degree of thrombocytopenia or persists after the platelet count returns to normal, suggesting that the bound antibody is perturbing platelet function.[291]

In some patients with ITP or SLE, platelet dysfunction may be suspected because mucocutaneous bleeding symptoms occur despite platelet counts that are usually sufficient for normal hemostasis (greater than 50,000/μL), and the bleeding time may be longer than expected for the degree of thrombocytopenia. Patients with antiplatelet antibodies can exhibit defective platelet function in vitro even if they do not have prolonged bleeding times or clinical symptoms of excessive bleeding, a situation similar to what occurs with ASA ingestion or renal disease. For example, in two studies, 13 of 19 patients with ITP demonstrated impaired platelet aggregation to ADP, epinephrine, or collagen.[292,293] In two other studies, 22 of 35 patients with SLE were found to have decreased platelet aggregation in response to these agonists.[294,295] The platelet function abnormalities appear to be antibody-mediated because IgG purified from the plasma or eluted from the platelets of these patients inhibited the aggregation of normal platelets.

Platelet antibodies may affect several aspects of platelet function. The most frequently observed abnormality is the absence of platelet aggregation in response to low concentrations of collagen and the absence of the second wave of aggregation in response to ADP or epinephrine. This pattern is identical to the abnormalities caused by ASA, described earlier. In ITP and SLE, the abnormal aggregation may be related to a reduction in the contents of dense and α granules, or to an activation defect manifested by diminished synthesis of TXA_2.

Autoantibodies or alloantibodies usually impair the function of the antigen against which they are targeted. For example, alloantibodies (e.g., anti-PlA1) and autoantibodies that bind to αIIbβ3 produce a syndrome similar to Glanzmann thrombasthenia.[296–300] These antibody-associated thrombopathies can be severe.[301]

It is not surprising that many of the antiplatelet antibodies target $\alpha_{IIb}\beta_3$ because this is the most abundant receptor on the platelet surface and is required for all aggregation responses.[302] Antibodies that target GPIb have also been described, in one case producing a syndrome of severe refractory thrombocytopenia and a functional defect resembling that observed in Bernard-Soulier syndrome.[303] An interesting aspect of antibodies against GPIb is their association with more severe thrombocytopenia than that observed with antibodies directed against other antigens.[304] This finding is consistent with the observations that anti-GPIb antibodies inhibit megakaryopoiesis[305] and proplatelet formation in vitro.[306] Autoantibodies have been described that target GPIa (integrin α2),[307,308] GPIV,[308] and GPVI.[309–311]

Platelet-activating antibodies have been described. Of particular interest is the report of a patient who presented with immune thrombocytopenia and an antibody against CD9 (a member of the tetraspanin protein family) that could activate normal platelets.[312] After recovery of the platelet count, the patient relapsed, this time with an antibody described against the platelet Fc receptor, FcγRIIA. The latter antibody blocked the capacity of the first antibody to activate platelets, confirming that activation involved stimulation of the Fc receptor.

Platelets that have been activated and induced to secrete but have not been incorporated into aggregates are likely to be refractory to platelet agonists and deficient in secretory granule contents, essentially leading to an acquired storage pool deficiency, which has also been described in association with autoantibodies.[313]

Acquired Platelet Dysfunction With Eosinophilia

Acquired platelet dysfunction with eosinophilia is a self-limited disorder characterized by mucocutaneous bleeding and hyper-eosinophilia.[314,315] The platelet count is usually normal; however, the platelets are pale by light microscopy (as in gray platelet syndrome), and aggregation studies show an acquired storage pool defect. All reported cases have been from South-East Asia. In some cases, eosinophilia and platelet dysfunction returned to normal after anti-helminthic therapy, which suggests a parasitic infection.[316]

CHAPTER 129

DISEASES OF PLATELET NUMBER: IMMUNE THROMBOCYTOPENIA, NEONATAL ALLOIMMUNE THROMBOCYTOPENIA, AND POSTTRANSFUSION PURPURA

Michelle P. Zeller, Shuoyan Ning, Donald M. Arnold, and Caroline Gabe

Platelets are anucleate cells that are required for primary hemostasis. A normal platelet count is 150,000 to 400,000 platelets per microliter of blood, with a normal lifespan of 7 to 10 days for circulating platelets. The body clears 10^{11} platelets per day by balancing complex proapoptotic and antiapoptotic mechanisms. Exogenous reagents and environmental changes can also impact the rate of platelet clearance[1] by the cells of the reticuloendothelial system (RES), including the spleen.

Platelet production is stimulated by thrombopoietin (TPO), a hormone that is constitutively secreted by the liver. TPO binds to c-Mpl, its receptor on platelets, hematopoietic progenitor cells, and bone marrow (BM) megakaryocytes. When bound to c-Mpl, TPO is internalized, degraded, and removed from the circulation; thus, when the platelet count is low, free TPO levels are high and more platelets are produced. In contrast, when platelet counts are high, circulating TPO levels are low and platelet production declines. This primitive feedback system is very effective at maintaining the platelet count at a stable level. Evidence in mice has shown that the Ashwell-Morell receptor on murine hepatocytes binds platelets that have lost sialic acid residues on their surface.[2] Binding activates a Janus kinase/signal transducer and activator of transcription (JAK/STAT) signaling pathway, resulting in increased hepatic TPO messenger RNA (mRNA) expression and TPO production. Targeting this pathway may become a therapeutic approach for the treatment of thrombocytopenic disorders such as immune thrombocytopenia (ITP).

Immune-mediated platelet disorders disrupt normal regulation of platelet number because of antibody-mediated or cell-mediated platelet destruction or platelet underproduction. Antibodies that target self (autoimmune) or nonself (alloimmune) antigens on platelets can cause severe thrombocytopenia. ITP is an autoimmune disorder characterized by antibodies directed against platelet glycoproteins (GPs). Neonatal alloimmune thrombocytopenia (NAIT) is a thrombocytopenic syndrome caused by platelet alloantibodies. Posttransfusion purpura (PTP) has features of both alloantibody- and autoantibody-mediated processes. These platelet disorders have related immunologic features with distinct clinical characteristics (Table 129.1). The pathophysiology, clinical manifestations, and management of these disorders are discussed in this chapter.

IMMUNE THROMBOCYTOPENIA

ITP is a common autoimmune disease characterized by a platelet count less than 100×10^9/L that can be associated with an increased risk of bleeding. Increased platelet destruction resulting from platelet autoantibodies is a hallmark of ITP, but many patients with the clinical syndrome do not have detectable autoantibodies. In addition to platelet destruction, platelet underproduction is also a feature of ITP. Platelet underproduction may also be mediated by immune mechanisms that target megakaryocytes in the BM.[3] Conventional treatments, including corticosteroids, intravenous immunoglobulin (IVIg), immunosuppressant medications, and splenectomy, are aimed at reducing the autoimmune attack on platelets and/or megakaryocytes. Likewise, fostamatinib targets platelet destruction by inhibiting Syk (spleen tyrosine kinase), which is required for platelet phagocytosis. On the other hand, TPO receptor agonists (RAs) are megakaryocyte growth factors that work by increasing platelet production.

Epidemiology

The natural history of ITP differs in children and adults. In most children, ITP presents acutely and resolves within several weeks, often not requiring any intervention. Seasonal variability suggests that viral infections may trigger the disease in many children. Conversely, ITP in adults tends to be insidious in onset and is more often characterized by a chronic or remitting and relapsing course.

Incidence and Prevalence of Immune Thrombocytopenia

For children, the incidence of acute ITP is estimated at 1.9 to 6.4 per 100,000 per year.[4] Nearly 70% of childhood ITP occurs between the ages of 1 and 10 years, with the peak prevalence between 4 and 6 years. Most studies in children report an overall male predominance in early childhood and equalization or reversal to female predominance in older children.[5,6] For adults, incidence estimates range from 2 to 5 per 100,000 per year.[4–8] A retrospective analysis from the United Kingdom described a bimodal distribution for men, with peak incidences before the age of 18 years and between 75 and 84 years of age.[7] Relatively stable incidence rates were found in women up to the age of 60 years with a steady increase thereafter. The incidence of ITP has been reported to double in patients older than 60 years of age. The estimated overall prevalence of ITP in adults is 9.5 per 100,000, and it ranges from 4.1 per 100,000 in those between 19 and 24 years of age to 16 per 100,000 in those between 55 and 64 years of age.[5] There is a female predominance that is less apparent in older age groups.

Pathophysiology

ITP is caused by increased platelet destruction and impaired platelet production, and the principal mechanism is thought to be due to autoantibodies. The antibody hypothesis began with the observation that blood from patients with ITP was able to cause a reduction in the platelet count in healthy volunteers. In one of the first experiments, William Harrington infused blood from ITP patients into normal volunteers and observed a decrease in the platelet counts in most recipients.[9] The circulating factor responsible for this effect was first identified as platelet-associated immunoglobulin G (PAIgG). With the development of more specific assays, it was determined that the antibodies were directed against platelet GPs, specifically GPIIbIIIa and GPIbIX. GP-specific assays for the detection of autoantibodies exhibited improved specificity but had low sensitivity (50% to 66%), meaning that many ITP patients had a negative test and only ITP

TABLE 129.1 **Antibody-Mediated Thrombocytopenic Disorders Caused by Autoantibodies (Immune Thrombocytopenia), Alloantibodies (Neonatal Alloimmune Thrombocytopenia) or Potentially Both (Posttransfusion Purpura)**

	Immune Thrombocytopenia	Neonatal Alloimmune Thrombocytopenia	Posttransfusion Purpura
Immune reaction	Autoimmune	Alloimmune	Features of both alloimmunity and autoimmunity
Incidence	5 per 100,000 population	40 per 100,000 births (or 1 per 2500)	1 per 100,000 blood transfusions
Principal antigenic target	GPIIb/IIIa	HPA-1a	HPA-1a plus autoantigens
Nature of the antibody	Intermittent	Persistent (past 1 year)	Persistent often at high titers
Mode of sensitization	Autoantibody	Alloantibody	Features of alloantibodies and autoantibodies
Sensitizing event	Mostly unknown; some viral illnesses, chronic infection	Exposure to fetal platelet antigens early in first pregnancy	Blood transfusion (RBCs or platelets) 5–10 days earlier
Bleeding frequency	Uncommon	Common	Very common
Epidemiology	Higher incidence in children and elderly adults; female predominance in early adulthood	Majority affects fetus or newborn carrying the HPA-1a antigen	Almost all are HPA-1bb women sensitized by previous transfusion or pregnancy

GP, Glycoprotein; *HPA*, human platelet antigen; *RBC*, red blood cell.

patients had a positive test. Anti-GP autoantibodies target platelets for destruction in the RES by binding to the Fc-receptor on phagocytic cells, particularly the spleen. Peptides from phagocytosed platelets may be processed and presented to specific T cells, which in turn stimulate B cells to produce additional platelet autoantibodies. This process, known as epitope spreading, may explain why patients have circulating autoantibodies targeting a variety of platelet antigens. Antibody-induced platelet destruction in ITP can also be caused by complement activation and platelet apoptosis.

The low sensitivity of platelet antibody testing (anti-GPIIbIIIa or anti-GPIbIX) may be explained by the presence of autoantibodies against other target proteins (e.g., anti-GPV, which was found in 64.7% of patient samples in one cohort study[10]), low-avidity platelet antibodies, or the sequestration of autoantibodies in other body compartments. In a study of 18 patients with ITP, 10 (56%) had antiplatelet antibodies detectable in BM aspirate fluid, including 5 patient who did not have detectable circulating antibodies.[3] Similarly, a study of spleen tissue from patients with ITP identified antibody-secreting cells as the major splenic B-cell population in patients who were refractory to rituximab.[11]

In addition to accelerated platelet destruction, platelet production also may be impaired in ITP. Evidence supporting reduced platelet production derives from radiolabeled autologous platelet studies demonstrating normal or reduced platelet turnover[12] and from clinical studies that have consistently demonstrated the capacity of TPO-RAs to increase platelet counts in patients with severe thrombocytopenia. Megakaryocytes also express GP receptors, which render them targets of ITP autoantibodies. Indeed, in vitro studies demonstrated suppression of megakaryocyte growth and maturation when the cells were incubated with IgG from ITP patients.[13–15]

In addition to the effect of autoantibodies, cytotoxic T cells from ITP patients may have direct cytolytic effects on platelets. Some patients with active ITP but without detectable platelet autoantibodies had $CD8^+$ T cells that induced platelet lysis in vitro.[16,17] In contrast, $CD8^+$ T cells from patients in remission did not show significant platelet reactivity. In another study, despite demonstrating the increased cytotoxic potential of $CD8^+$ T cells in a sample of patients with ITP, no correlation was found between this cytotoxic potential and the presence or absence of platelet antibodies.[18] Furthermore, compared with cells from controls, $CD3^+$ cells from ITP patients exhibited increased expression of genes involved in cell-mediated cytotoxicity, including tumor necrosis factor-α (TNF-α), perforin, and granzyme A and B, and $CD8^+$ T cells exhibited increased expression of FasL (Fas–Fas ligand) and TNF-α.[17]

Another mechanism of thrombocytopenia in ITP is non–FcR-mediated platelet destruction. Platelet autoantibodies have been shown to cause desialylation of platelet GPs, leading to recognition and clearance of platelets in the liver by the Ashwell-Morell receptors.[2,19] Antibody-mediated desialylation may also impair platelet production.[2]

In the broadest sense, autoimmunity develops because of a breakdown in regulatory checkpoints that occurs during development or maturation of the immune system. Although the precise events that trigger the loss of self-tolerance to platelet GPs are largely unknown, patients with ITP have been shown to exhibit several immune alterations to platelet antigens including dysfunctional cellular immunity because of T helper (Th)0/Th1 polarization, decreased regulatory T-cell function, and autoreactive platelet-specific cytotoxic T cells. In addition, ITP patients may have increased circulating levels of cytokines and soluble factors that promote the survival of self-reactive T and B cells, including B-cell activating factor, a proliferation-inducing ligand, and B-cell lymphoma-2–interacting mediator of cell death. Reduced levels of proapoptotic cytokines that regulate self-reactive T cells, including Fas, interferon-γ, interleukin-2 receptor β (IL2RB), Bax, and caspases 8 and A20, have also been demonstrated.

Primary and Secondary Immune Thrombocytopenia

Primary ITP, previously called idiopathic thrombocytopenic purpura, occurs in the absence of an identifiable cause. Secondary ITP occurs because of an underlying cause such as infection, pregnancy, drugs, or lymphoproliferative disease (see box on Causes of Secondary ITP).

Infection may stimulate the formation of platelet-reactive autoantibodies. Cross-reactive antibodies (molecular mimicry) have been identified in *Helicobacter pylori*, human immunodeficiency virus (HIV), and hepatitis C virus (HCV) infections. Regarding *H. pylori*, a meta-analysis that included 788 patients showed that *H. pylori* eradication resulted in higher platelet counts in ITP patients compared with untreated or noneradicated controls.[20] Another systematic review evaluating 696 patients reported that 43% of treated patients achieved platelet counts greater than 100×10^9/L; however, the effect was highly dependent on geographic location, with the beneficial effect mainly observed in patients from Japan.[21] There is no clear guidance on when to screen for *H. pylori*. Guidelines from the American Society for Hematology[22,23] suggest that screening be considered for patients with ITP for whom eradication therapy would be

CAUSES OF SECONDARY IMMUNE THROMBOCYTOPENIA

Infections—HIV, HCV, *Helicobacter pylori*

Autoimmune disorders—SLE, APS, RA, Evan syndrome

Lymphoproliferative disorders

Drugs[a]—quinine, quinidine, rifampin, abciximab, vancomycin

used. The most recent ITP consensus report recommends testing for *H. pylori* in adults with typical ITP, in those with digestive symptoms, and those from areas of high prevalence.[24]

ITP also may present in the setting of pregnancy. Mild ITP may be difficult to differentiate from incidental thrombocytopenia of pregnancy, and pregnancy-related vascular disorders, such as preeclampsia, microangiopathy caused by HELLP syndrome (characterized by hemolysis, elevated liver enzymes, and a low platelet count), and acute fatty liver must be excluded. In these pregnancy-related disorders, platelet counts tend to be mildly reduced and hypertension is common. Incidental thrombocytopenia of pregnancy (also called *gestational thrombocytopenia*) represents a physiologic change in platelet count that occurs late in pregnancy and is associated with a mild reduction in platelet count, which does not respond to immune-modulating therapy. In contrast, pregnancy-associated ITP may present at any time during pregnancy, and the thrombocytopenia can range from mild to severe. Typically, platelet counts increase with ITP-specific therapies such as IVIg or corticosteroids. Platelet count thresholds for instituting treatment are the same as those for women with ITP who are not pregnant (e.g., platelet count less than 20×10^9/L). Vaginal deliveries are thought to be safe for mothers with ITP, even if the platelet count is very low, and most clinicians try to maintain the count greater than 20 to 30×10^9/L. A higher platelet count is generally recommended for caesarean section delivery (50×10^9/L) and epidural anesthesia (70 to 80×10^9/L). Although evidence is lacking, IVIg and corticosteroids are generally safe in pregnancy, but corticosteroids can be associated with hypertension, gestational diabetes, intrauterine growth restriction, and other pregnancy-associated morbidities. Splenectomy is rarely performed during pregnancy because most women can successfully be managed with less-aggressive treatments. Immunosuppressant medications, such as azathioprine, have been used in pregnancy but should be reserved for refractory pregnancy-associated ITP with bleeding. Rituximab is not recommended during pregnancy, although it is likely to be safe. Rituximab may interfere with fetal and neonatal B-cell development, which may lead to increased susceptibility to infections. TPO-RAs may be considered in exceptional circumstances during pregnancy if other treatments have failed and the risk of severe bleeding is high. For mothers with active ITP or even with ITP that is in remission, there is a 10% risk of thrombocytopenia in the newborn because of passive transfer of maternal antiplatelet autoantibodies.

Clinical and Laboratory Features of Immune Thrombocytopenia

Thrombocytopenia

Thrombocytopenia is the defining feature of ITP. The international working group on standardization of terminology in ITP established a platelet count less than 100×10^9/L as the cutoff for the diagnosis (Table 129.2).[25] Primary ITP remains a diagnosis of exclusion because there is no specific test to confirm the diagnosis. Investigations for patients with thrombocytopenia are used to rule out nonimmune causes, including pseudothrombocytopenia, myelodysplastic syndromes, thrombotic microangiopathies, liver disease, splenomegaly, certain drugs, ethanol abuse, or hereditary thrombocytopenia; and secondary causes of ITP such as infection, concomitant autoimmune disease, or lymphoproliferative disorders. Data from a Canadian ITP Registry showed that one in seven patients suspected of having primary ITP was misdiagnosed during their disease.[26] Response to ITP-specific treatment (e.g., high-dose IVIg or high-dose corticosteroids) is generally considered a good indicator of immune-mediated thrombocytopenia.

TABLE 129.2 **Standardized Terminology and Definitions for Immune Thrombocytopenia Proposed by the International Working Group (Vicenza Consensus Conference) in 2009 and ASH Guideline 2019**

Terminology	Definition
ITP	Immune thrombocytopenia (rather than idiopathic or immune thrombocytopenic purpura)
Platelet threshold for ITP diagnosis	$<100 \times 10^9$/L
Primary ITP	ITP with no associated cause (diagnosis of exclusion)
Secondary ITP	ITP in the setting of an underlying cause (see box on Causes of Secondary ITP)
Newly diagnosed ITP	Designation for patients at diagnosis (rather than "acute" ITP) up to 3 months of the diagnosis
Persistent ITP	Sustained or recurrent thrombocytopenia lasting 3–12 months
Chronic ITP	Thrombocytopenia lasting >12 months
Complete response	Achievement of a platelet count of $\geq 100 \times 10^9$/L in the absence of bleeding
Response	Achievement of a platelet count of $\geq 30 \times 10^9$/L and at least doubling baseline in the absence of bleeding
Early response	Achievement of a platelet count $\geq 30 \times 10^9$/L and at least doubling baseline at 1 week
Initial response	Achievement of a platelet count $\geq 30 \times 10^9$/L and at least doubling baseline at 1 month
Durable response	Achievement of a platelet count $\geq 30 \times 10^9$/L and at least doubling baseline at 6 months
Corticosteroid-dependent	Ongoing need for continuous prednisone >5 mg/day (or corticosteroid equivalent) or frequent courses of corticosteroids to maintain a platelet count $\geq 30 \times 10^9$/L and/or to avoid bleeding
Refractory ITP	Failure to achieve a response or relapse after splenectomy[a] and requirement for treatment(s) to minimize the risk of clinically significant bleeding
Remission	Platelet count $>100 \times 10^9$/L at 12 months

[a] Splenectomy failure may not be applicable in children.

ITP, Immune thrombocytopenia.

Clinical Features

The clinical presentation of ITP can range from asymptomatic thrombocytopenia to severe or life-threatening bleeding. When bleeding occurs, bleeding symptoms characteristic of ITP ("platelet-type bleeding") include skin bleeding (i.e., bruises, nonpalpable purpura, or petechiae), oral hemorrhagic blood blisters or oral petechiae, epistaxis, menorrhagia, or gastrointestinal bleeding manifested usually by melena. In addition to oral purpura, hematuria may be an important warning sign for major bleed, as demonstrated in a recent retrospective cohort study.[27] The most severe complication of ITP is intracerebral hemorrhage (ICH).

Investigations of Patients With Suspected Immune Thrombocytopenia

Patients presenting with newly identified thrombocytopenia require a careful history and physical examination to uncover the underlying cause of the thrombocytopenia and to assess the risk of bleeding. If splenomegaly is present on physical examination, the thrombocytopenia may be caused by hypersplenism, and imaging is warranted. A panel of laboratory tests are needed to identify possible causes of the thrombocytopenia (see box on Laboratory Basic Evaluation for Patients With Suspected ITP). A complete blood count and review of the blood film are required to exclude other hematologic conditions, such as hereditary forms of thrombocytopenia (e.g., May-Hegglin) or pseudothrombocytopenia (Fig. 129.1). HIV and HCV testing should be performed in patients with suspected ITP, and *H. pylori* testing should be considered in patients from certain countries (e.g., Japan). Hepatitis B testing at baseline is reasonable if immunosuppressive treatments such as rituximab are being considered and to exclude the possibility of false-positive anti–hepatitis B core antibody testing after IVIg.[28] There are insufficient data to support routine screening for antinuclear antibodies or antiphospholipid antibodies unless other signs and symptoms of systemic lupus erythematosus or antiphospholipid syndrome are present. BM aspiration and biopsy should be done for patients with abnormalities in other cell lines such as anemia, leukopenia, or macrocytosis; however, most patients with typical ITP do not require BM examination. Quantitative Ig levels may be useful in children to exclude common variable immune deficiency. Thyroid testing can uncover subclinical hypothyroidism or hyperthyroidism that can lead to mild thrombocytopenia. Coagulation tests such as

D-dimer, partial thromboplastin time (PTT), and fibrinogen may be helpful in excluding chronic disseminated intravascular coagulation in patients with malignancy (see Chapter 126). Antiplatelet antibody tests are rarely used in routine clinical practice.

Prognosis

Clinical Outcomes: Mortality, Bleeding, and Quality of Life

Chronic ITP has been associated with a risk of death that is up to four times higher than that in the general population. ITP patients are more likely to die of bleeding, infection, and hematologic malignancies. In a systematic review of prospective studies, the incidence of ICH was 1.4% for adults (95% confidence interval [CI], 0.9 to 2.1) and 0.4% for children (95% CI, 0.2 to 0.7).[29] The proportion of patients with severe (non-ICH) bleeding was 10% for adults (95% CI, 4.1 to 17.1) and 20% for children (95% CI, 10.0 to 32.9). Risk factors for severe bleeding include severe thrombocytopenia, previous bleeding, and older age. Another recent study also identifies male sex and heavily pretreated ITP as potential risk factors for major bleeding.[27] Some deaths are attributable to adverse effects of treatment rather than the disease. Quality of life is affected, at least in part, because of the prevalence of fatigue that appears to be independent of platelet count levels.

Treatment

Most patients with platelet counts greater than 30 × 10^9/L and without bleeding can be managed safely with observation alone. This is especially true for children with ITP who are at low risk of serious bleeding. Furthermore, in up to 80% of cases, childhood ITP resolves within 6 months with no treatment. If patients present with bleeding, such as epistaxis or mucosal hemorrhage, treatment is required. For adults, a period of observation is reasonable if there is no evidence of bleeding and the platelet count is stable and greater than 30 × 10^9/L, because some patients will have spontaneous remission.[30] The American Society of Hematology (ASH) 2019 guidelines recommend treatment for newly diagnosed ITP patients who are asymptomatic or have minor mucocutaneous bleeding with a platelet count less than 30 × 10^9/L.

Treatment Options

Corticosteroids with or without IVIg are first-line treatments for patients with newly diagnosed ITP. Treatment options for second-line therapies include rituximab, splenectomy, TPO-RAs, fostamatinib, and immune suppressant medications. We recommend an approach that uses the least toxic treatments with the aim of resolving bleeding or preventing severe bleeding and that aligns with patient preferences to optimize health-related quality of life (Fig. 129.2, and see Box on Treatment Options for ITP and box on First-Line Therapy).

Treatment options

Figure 129.2 Selection of second-line therapy in adults with immune thrombocytopenia (ITP) should be individualized based on duration of disease and patient values and preferences. Other factors that may influence treatment decisions include frequency of bleeding sufficient to require hospitalization or rescue medication, comorbidities, compliance, medical and social support networks, cost, and availability of treatments. Patient education and shared decision-making is encouraged. *TPO-RA*, Thrombopoietin receptor agonist. *(From Neunert C, Terrell DR, Arnold DM, et al. TREATMENT OPTIONS FOR IMMUNE THROMBOCYTOPENIA

First Line

IVIg

Corticosteroids

Anti-D

Second Line

Rituximab

TPO agonists

Splenectomy

Fostamatinib

Immunosuppressive/immunomodulatory medications (mycophenolate, cyclosporine, azathioprine and others)

ITP, Immune thrombocytopenia; *IVIg*, intravenous immunoglobulin; *TPO*, thrombopoietin.

FIRST-LINE THERAPY

An 8-year-old girl is brought to the emergency department because her mother noticed bruising on her legs. She has had a sore throat and fever for the past 7 days but is otherwise well and not taking any medications. On physical examination, there are a few small bruises on her legs but no petechiae on her skin or purpura in her mouth. Neurologic examination findings are normal, and the spleen is not palpable. The platelet count is 23 × 10^9/L. The presumed diagnosis is ITP without significant bleeding; thus the decision is made to observe the child in the hospital with no specific treatment. The next day, the platelet count is 33 × 10^9/L. On day 2, it is 37 × 10^9/L, and the child is discharged home. One week later, the platelet count is 66 × 10^9/L, and 1 month later, it is up to 155 × 10^9/L.

Corticosteroids

The conventional starting dose is predniso(lo)ne at 0.5 to 2 mg/kg (maximum dose 80 mg, even in patients weighing more than 80 kg) for 2 weeks, to a maximum of 3 weeks; or dexamethasone 40 mg/day for 4 days, repeated monthly for up to three cycles. In general, 60% to 70% of adults with acute ITP achieve an initial response with corticosteroids. If a response occurs (e.g., platelet count imp >50 × 10^9/L), the predniso(lo)ne dose should be tapered, aiming to stop by 6 weeks. The course of corticosteroids should be tapered and stopped even if the platelet count drops during the period of drug treatment to avoid prolonged exposure to corticosteroids. If there is no response to the initial dose within 2 weeks, the predniso(lo)ne should be tapered rapidly over 1 week and stopped to limit the side effects. Sustained platelet count responses (platelet count >100 × 10^9/L at 6 months) with corticosteroids are infrequent in practice but have been reported to be as high as 47% in some studies. The risk of relapse increases with longer duration of follow-up. Low-dose prednisone (0.5 mg/kg/day followed by a taper) may be as effective as the conventional dose for initial ITP treatment, but long-term remissions are rare.

High-dose dexamethasone is also effective, and in one study that included 125 adults with ITP, approximately 40% of patients had a sustained response that lasted 2 to 5 years.[31] Repeated cycles of high-dose dexamethasone (once per month for 6 months) may result in even higher rates of durable remissions, although this effect may simply reflect the total corticosteroid exposure. High-dose dexamethasone is associated with side effects including hypertension, muscle weakness, insomnia, and impaired cognition. In a systematic review of randomized trials comparing high-dose dexamethasone and prednisone in adults with previously untreated ITP ($n = 533$), treatment with dexamethasone resulted in improved overall (79% vs. 59%; $P = 0.048$) and complete platelet count responses (64% vs. 36%; $P = 0.040$) without excess toxicity.[32] Platelet count responses occurred more rapidly with high-dose dexamethasone than with prednisone (within 14 days); however, sustained responses at 6 months were similar between the groups.

Intravenous Immunoglobulin and Rh-Immune Globulin (Anti-D)

The predominant mechanism of action of high-dose IVIg and anti-D is thought to be via RES blockade. Individuals with low plasma IgG levels exhibit more rapid clearance of sensitized red blood cells (RBCs) (indicating enhanced RES capacity) than those with high levels of plasma IgG, such as those achieved with high-dose IVIg. A competitive model of RES clearance would also explain why anti-D administration to Rhesus (Rh)-positive individuals is effective in improving platelet counts in patients with ITP. Thus IgG-sensitized RBCs compete for Fc receptor occupancy. Other potential mechanisms of action of IVIg or anti-D include antiidiotypic antibodies, stimulation of proinflammatory and antiinflammatory cytokines, upregulation or downregulation of various Fc receptors, and the induction of soluble immune complexes. In a mouse model of ITP, transfer of IVIg-primed dendritic cells recapitulated the effect of IVIg.

IVIg (1 g/kg on 1 or 2 consecutive days or 0.4 g/kg/day for 5 days) or intravenous (IV) anti-D (50 to 75 mg/kg once), where available, may be appropriate options for patients with bleeding or at high risk for bleeding, for those who require a surgical procedure (as the response is usually achieved in a few days), or for those who are unresponsive to corticosteroids. Based on the results of a meta-analysis of randomized controlled trials that included 410 children, the probability of achieving a platelet count greater than 20 × 10^9/L at 48 hours was higher with IVIg than with corticosteroids (relative risk for corticosteroids, 0.74; 95% CI, 0.65 to 0.85).[33] Similar results were observed in adults. Common side effects of IVIg include headache, hypertension, and chills. Hemolysis, thrombosis, renal impairment, and neutropenia are rare complications.

Anti-D and IVIg have similar efficacy in children. Hemolysis is expected with anti-D administration, and rarely, intravascular hemolysis can be severe or even fatal. Consequently, the US Food and Drug Administration (FDA) has issued a black box warning about the use of anti-D for the treatment of ITP, and the drug has been removed from certain European markets. In general, the use of anti-D is restricted to patients who have not undergone splenectomy, are Rh-positive, and have a negative direct antiglobulin test.

Second-Line Therapy

Randomized trials comparing different treatment options for second-line therapy for ITP are lacking; therefore the decision as to which therapy to choose depends on the goals of therapy (remission vs. maintenance), patient characteristics, patient preference, access, and costs. Despite advances in medical care and new pharmacologic treatment options, splenectomy remains the treatment that is most likely to induce a durable remission; however, the use of splenectomy has declined in recent years. TPO-RAs including romiplostim, eltrombopag, and avatrombopag; rituximab; and fostamatinib are reasonable second line treatments for ITP.

Splenectomy

In a systematic review, approximately two-thirds of patients achieved a platelet count response after splenectomy, usually within days.[34] Despite the high success rate with splenectomy, patients (and physicians) are often reluctant to undertake an invasive procedure such as splenectomy when pharmacologic alternatives are available. Only younger age has been identified as a predictor of splenectomy success, although some investigators have found a correlation between prior response to IVIg and a splenic uptake on radiolabeled platelet sequestration studies.[35]

With currently available minimally invasive surgical techniques, complications after splenectomy are uncommon. The overall mortality rate is approximately 1% with open surgery and about 0.2% after laparoscopic splenectomy. The most frequent perioperative complications include pneumonia, subphrenic abscess or pleural effusion

(4%), major bleeding (1.5%), and thromboembolism (1%). With laparoscopic techniques, patients have less postoperative pain, shorter hospital stays, and fewer wound complications.

Because the spleen is involved in clearance of encapsulated bacteria, asplenic individuals are at risk for infection with *Streptococcus pneumoniae, Neisseria meningitides*, and *Haemophilus influenzae* type b. Therefore all patients undergoing splenectomy should receive vaccinations against these bacteria at least 2 weeks before surgery. Poor compliance and vaccine failures contribute to the ongoing risk of serious postsplenectomy infections. The lifetime risk of overwhelming postsplenectomy infection is estimated to be 1% to 3%, with the risk being higher in children younger than 15 years of age and in patients with hematologic malignancies. Although the risk of an infection requiring hospitalization was highest in the first 90 days after splenectomy in a cohort of 3812 patients in Denmark,[36] the risk remained 2.5 times higher than that in the general population even after 90 days. Because approximately 20% of patients can achieve a remission within the first year of the ITP diagnosis, it is prudent to wait at least 12 months before splenectomy.

Splenectomy can lead to a high rate of durable remission. In a systematic review, 1731 of 2623 adults (66%) with ITP achieved a complete response after splenectomy at a median follow-up of 28 months (range 1 to 153 months), and this response rate was maintained for 10 years or more.[34]

Disadvantages of splenectomy include a lack of validated predictors of response, surgical risk with 30-day mortality and complication rates of 0.2% and 9.6% for laparoscopic splenectomy, respectively, and 1.0% and 12.9% for open splenectomy, respectively, and an increased risk of postsplenectomy infection, and vascular thrombosis.[34] In the past decade since the introduction of new pharmacologic options including the TPO-RAs, the use of splenectomy has continued to decline.

Rituximab

Rituximab has been widely used in patients with various autoimmune diseases, including ITP. Rituximab is an anti-CD20 monoclonal antibody that targets and destroys CD20$^+$ B lymphocytes, some of which are likely involved in autoantibody production. Data correlating cellular profiles with clinical outcomes suggest that the efficacy of rituximab reflects improvement in T-cell function and reversion of T-cell abnormalities; processes downstream to its direct effect on B-cell depletion.

In a systematic review of 19 observational studies that enrolled 313 ITP patients of whom 46% had not undergone splenectomy, rates of complete response (platelet count $>150 \times 10^9$/L) and overall response (platelet count $>50 \times 10^9$/L) with rituximab after a median follow-up of 9.5 months were 44% (95% CI, 30 to 58) and 63% (95% CI, 53 to 73), respectively.[37] The typical rituximab regimen was 375 mg/m^2 administered by IV infusion once weekly for 4 consecutive weeks. The median time to response was 5.5 weeks, with some responses occurring much later (up to 8 to 12 weeks), and a median duration of response of 10.5 months. Several studies have shown that patients who are earlier in their disease course (<12 months), female patients, younger patients (<40 years), and patients with underlying autoimmune conditions may be more likely to achieve a complete response after rituximab.[38] Other observational studies have reported lower rates of durable remission, ranging from 24% at 12 months to 35% at 57 months. A meta-analysis of five randomized trials demonstrated that complete platelet count response was more frequent with rituximab plus standard of care than with standard of care alone (relative risk 1.4, 95% CI, 1.1 to 1.8); however, there was limited evidence for sustained platelet count responses beyond 6 to 12 months.[39]

In a prospective observational study that included 60 adults with ITP who had not undergone splenectomy and who had a median of two prior therapies, 24 (40%) achieved a platelet count greater than 50×10^9/L and at least twice their baseline value at 1 year, and 20 (33%) maintained their platelet count response at 2 years with rituximab treatment.[40] In a follow-up study of 72 adults and 66 children with chronic ITP who achieved an initial response to rituximab, 21% to 26% maintained a treatment-free response for at least 5 years.[41] Low-dose rituximab (100 mg/week for 4 weeks) has been shown to be effective in ITP, but the frequency of durable responses is uncertain.

Minor infusion-related side effects of rituximab occur in approximately 30% of patients with ITP and include hypotension, rash, sore throat, fever, and rigors. Severe or fatal infusion reactions are rare in patients treated for autoimmune diseases. Serum sickness, which is characterized by arthropathy, fever, and low serum complement levels, may be more common in children than in adults and often necessitates treatment interruption. Progressive multifocal leukoencephalopathy (PML) is a rapidly fatal neurologic syndrome caused by reactivation of latent JC virus in the brain. Rare reports have linked PML with rituximab treatment.

Rituximab also interferes with the response to polysaccharide vaccines. This is of potential concern in patients who may subsequently undergo splenectomy and supports the practice of administering immunizations before initiating rituximab therapy. Rituximab has a role for patients with ITP who wish to avoid long-term therapy and the surgical risks of splenectomy; however, the durability of response may be less than that with the TPO-RAs or splenectomy.

Thrombopoietin Receptor Agonists

Drugs aimed at increasing platelet production by stimulating the c-Mpl receptor have been investigated for the treatment of thrombocytopenia. Initial studies with pegylated recombinant human megakaryocyte growth and development factor were halted because of the development of cross-reactive antibodies against endogenous TPO, which led to severe and sustained thrombocytopenia in some healthy volunteers. Although research with these specific agents was halted, the findings prompted the development of second-generation TPO-RAs that have no homology to endogenous TPO. Two TPO-RAs were approved for the treatment of patients with chronic ITP in 2008: romiplostim and eltrombopag. Since then, their use has increased progressively. In 2019 avatrombopag, another TPO-RA, was licensed for use in patient with chronic ITP. For this class of medications, the effect on platelet count is generally sustained if the TPO-RA is continued. When they are stopped, platelet counts tend to fall rapidly back to baseline levels; however, in recent studies, it has been reported that 10% to 30% of patients achieve a durable response after treatment discontinuation.[42,43]

Romiplostim (administered as a once-weekly subcutaneous injection) is a synthetic peptibody consisting of four peptides linked to an IgG Fc fragment. The molecule binds the c-Mpl receptor at the same location as endogenous TPO and stimulates megakaryocyte proliferation and platelet production through intracellular JAK/STAT and mitogen-activated protein kinase signaling. In a phase III trial, a durable platelet count response (defined as the achievement of a platelet count of 50×10^9/L or higher for 6 or more of the last 8 weeks of treatment) was achieved in 41 of 83 patients (49%) receiving romiplostim compared with 1 of 42 (2%) patients receiving placebo.[44] In a subsequent randomized trial that compared romiplostim plus standard of care with standard of care alone, romiplostim was associated with more platelet count responses, fewer treatment failures, fewer splenectomies, less bleeding, and better quality of life.[45] Weekly doses of romiplostim ranged from 1 to 10 μg/kg; however, most patients achieved a suitable response with a dose of 3 μg/kg. Weekly doses were titrated up or down to maintain the platelet count in the appropriate range (30 to 100×10^9/L).

Eltrombopag (administered as an oral daily tablet, 50 to 75 mg daily, >2 hours before or 4 hours after products containing polyvalent cations) is a small molecule, nonpeptide TPO-RA. Eltrombopag also activates the c-Mpl receptor, but unlike romiplostim, eltrombopag binds to the transmembrane domain of the receptor and does not compete with circulating TPO for binding. In a phase III trial, eltrombopag was associated with an eightfold increase in platelet count response compared with placebo throughout the 6-month treatment period.[46] The time to response was 1 to 2 weeks (like romiplostim), and there was minimal need for dose titration. Durable responses were achieved in 57 of 95 patients (60%) receiving maintenance eltrombopag and in only 4 of 39 patients (10%) receiving placebo.

Avatrombopag is another TPO-RA licensed for the treatment of chronic ITP in adults that binds to the transmembrane region of the TPO receptor and activates signal transduction pathways leading to increased platelet production, like eltrombopag. Unlike eltrombopag, avatrombopag does not interact with food or cations and has not been associated with liver enzyme elevations. A phase III study comparing avatrombopag with placebo in patients with chronic ITP demonstrated the safety and efficacy of avatrombopag, with a platelet response rate of 66% versus 0%, respectively.[47]

TPO-RAs are generally well tolerated but have been associated with headache, fatigue, and insomnia. The development of BM reticulin in patients with ITP was an early concern; however, this problem was rarely encountered in prospective studies and the changes improved with discontinuation of the medication. TPO-RAs have also been associated with thromboembolic events (independent of platelet count), with a rate of 7% for patients receiving romiplostin and 4% for eltrombopag. This risk may be somewhat higher than the baseline risk of thromboembolism in patients with ITP. Eltrombopag has been associated with serum liver function test abnormalities in approximately 10% of patients. Treatment-related serious adverse events were infrequent even after prolonged exposure to romiplostim ($n = 292$)[48] or eltrombopag ($n = 299$).[49]

A recent randomized trial evaluated the use of eltromobopag versus IVIg as treatments for ITP during the perioperative period ($n = 76$).[50] Eltrombopag was not inferior to IVIg and is therefore a reasonable alternative for raising the platelet count before surgery and during the immediate postoperative period. One patient had a treatment-related pulmonary embolism after eltrombopag.

Fostamatinib

Fostamatinib is a splenic tyrosine kinase inhibitor approved in 2018 by the FDA for treatment of chronic ITP. In a randomized trial of second-line therapy for patients with ITP for a median duration of ITP of 8.5 years, many of whom had failed splenectomy, TPO agents, and/or rituximab, fostamatinib was associated with a stable response (platelets $\geq 50 \times 10^9$/L for 4 of 6 weeks) in 18% of patients and on overall response (platelets $\geq 50 \times 10^9$/L at any time) in 43% of patients. The initial dose of fostamatinib was 100 mg twice daily. Response occurred in a median of 15 days. Diarrhea and hypertension were the most frequently reported side effects.[51,52]

Immune Suppressant Medications

Immune suppressant medications, such as mycophenolate, azathioprine, and cyclosporine, have variable response (varying from 25% to 70%), usually of short duration and delayed time to response (4 to 8 weeks). This group of medications is often reserved for chronic refractory ITP patients following TPO-RAs. However, a recent randomized trial comparing corticosteroids to a combination of mycophenolate mofetil and corticosteroids suggested that the addition of mycophenolate may result in a better response and lower risk of relapse or refractory disease, despite a decrease in quality of life.[53] Immune suppressant medications can sometime be more effective when given in combination as show in a retrospective study of 19 patients treated with the combination of azathioprine, mycophenolate mofetil, and cyclosporine. Overall response in that group of patients was 74%, and median time to response was 2 months (interquartile range, 1.3 to 4.5).[54]

Treatment of Refractory Immune Thrombocytopenia

As suggested by the International Working Group on standardization of terminology in ITP, the term *refractory ITP* is used to define patients who have failed splenectomy or relapsed thereafter and either exhibit severe thrombocytopenia or have a risk of bleeding that necessitates therapy (see Table 129.2).[25]

Evidence to help guide management of patients with chronic refractory ITP after splenectomy is limited, and treatment has been largely unsatisfactory. The overarching principle of therapy for this population is to prevent bleeding with the achievement of a stable, although not necessarily normal, platelet count. Combination therapy may be more effective than single agent treatment for achievement of this goal.

In randomized trials, patients with ITP who had not undergone splenectomy tended to show better platelet count responses to TPO-RAs than those who had; however, the difference was small, and response rates in patients who had undergone splenectomy approached 50%. Although some patients included in the trials had failed up to five prior therapies, the results may not be applicable to all patients with refractory ITP.

Before the availability of TPO-RAs, a systematic review identified rituximab, azathioprine, and cyclophosphamide as the agents most often associated with complete responses in patients with refractory ITP.[55] Good response rates have also been reported with a combination of cyclosporine, azathioprine, and mycophenolate, as mentioned earlier. Similarly, a combination of IVIg, IV methylprednisolone, vincristine, or IV anti-D followed by maintenance therapy with danazol and azathioprine has shown good response rates.[56] Other treatment options include low-dose or alternate-day corticosteroids, repeated doses of IVIg, high-dose chemotherapy, dapsone, and even the combination of romiplostin and eltrombopag. High-dose chemotherapy followed by stem cell transplantation has also been used successfully in this population, but with the advent of TPO-RAs, transplantation is no longer used.

COVID-19 and ITP

The coronavirus (SARS-Cov-2) pandemic raised several challenges for investigation of thrombocytopenia and management of ITP. Although thrombocytopenia may be present in up to 36% of patients hospitalized with COVID-19,[57] it is usually mild and only a minority of patients will present significant thrombocytopenia, which may be due to numerous potential causes. A retrospective study showed a very low incidence of ITP secondary to COVID-19 (0.34%) usually presenting after the first week of symptoms and with an excellent response to standard treatment (corticosteroids and IVIg).[58]

In the outpatient setting, corticosteroids have been discouraged as a treatment for ITP because of the potential risk for new or worsening COVID-19 infection. A practical guidance statement from the British Society of Haematology favored the use of TPO-RAs over immune-suppressive agents and suggested minimizing the dose and duration of corticosteroids.[59]

Rare thrombocytopenic syndromes have been described with the COVID-19 vaccines. Vaccine-induced immune thrombotic thrombocytopenia is a well-characterized immune-mediated thrombotic disorder caused by anti-PF4 antibodies that develop after exposure to the COVID-19 adenoviral vector vaccines.[60] A separate syndrome is vaccine-associated ITP, which has been reported after any of the COVID-19 vaccines and has a clinical presentation that is similar to primary ITP.[61] The frequency of vaccine-associated ITP has been estimated to occur be 1.13 per 100,000 doses,[62] but underreporting is likely. Patients with preexisting ITP have an increased risk of worsening thrombocytopenia after COVID-19 vaccination. In a prospective analysis of 52 patients with chronic ITP, 12% of patients had a drop in platelet count post vaccination, which was independent of remission status, concurrent ITP treatment, or vaccine type. All patients responded to rescue therapy with corticosteroids with or without IVIg.[63]

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

NAIT, also referred to as fetal and neonatal alloimmune thrombocytopenia (FNAIT), is an uncommon but serious fetal and neonatal thrombocytopenic disorder. Severe thrombocytopenia can lead to bleeding in utero or, during the neonatal period, resulting in death or significant morbidity. The incidence of NAIT has been estimated to range from 1:1000 to 1:10,000 births, although underdiagnosis is common. NAIT is an important condition to accurately recognize because treatment may prevent recurrences in any subsequent pregnancies.

Clinical Presentation

Thrombocytopenia is the key feature of NAIT. Thrombocytopenia may be profound in fetuses and neonates affected by NAIT, and in severe cases, the platelet count may be less than 10 to 20 × 10^9/L shortly after birth. In the neonatal setting, thrombocytopenia typically occurs in an otherwise healthy newborn without other causes for thrombocytopenia, outlined in Table 129.3, although the presence of other causes of thrombocytopenia does not exclude a diagnosis of NAIT. Thrombocytopenia will often worsen hours to days after delivery, likely reflecting increased RES function in the newborn, particularly within the lungs. Without treatment, neonatal thrombocytopenia may last for days, but it can be severe and persist for weeks before counts recover once the antiplatelet antibody levels decline. Clinical features depend on the severity of the thrombocytopenia. Bleeding symptoms range from petechiae and bruising to gastrointestinal, pulmonary, or retinal bleeding. Intracranial hemorrhage (ICH) is the most feared complication of NAIT; occurring in 10% to 20% of patients, ICH can occur in utero or after birth and carries significant mortality and morbidity. Predictors of ICH include a history of a sibling with ICH, severe thrombocytopenia, and children born to multigravidas.

Pathophysiology

In NAIT, fetal platelets contain a platelet antigen inherited from the father which the mother lacks. This prompts maternal IgG antibody formation against fetal/paternal platelet-specific antigens. Fetal and neonatal thrombocytopenia in NAIT thus reflects the clearance of IgG-sensitized fetal platelets by maternal alloantibodies; maternal IgG antibodies cross the placenta, bind fetal platelets, and cause clearance of the antibody-bound platelets by the RES, resulting in fetal thrombocytopenia. The syndrome can be considered analogous to the destruction of fetal RBCs in hemolytic disease of the fetus and newborn (HDFN) with several differences. First, NAIT often presents in a first pregnancy, possibly due to early maternal sensitization to paternally derived antigens expressed on fetal platelets. In contrast, it is uncommon for HDFN to occur in a first pregnancy without previous sensitization to paternally derived fetal RBC antigens. Second, pregnant women at risk for HDFN (e.g., with RBC antibodies) can be identified by routine antenatal antibody screens. Furthermore, anti-RhD immune globulin can be given prepartum and postpartum to RhD-negative women to reduce the risk of RhD sensitization. To date, screening programs for NAIT have not been widely implemented because women at risk are not readily identifiable before sensitization has occurred and therapies to prevent maternal alloimmunization are not available at this time (see box on Neonatal Alloimmune Thrombocytopenia Versus Hemolytic Disease of the Fetus and Newborn).

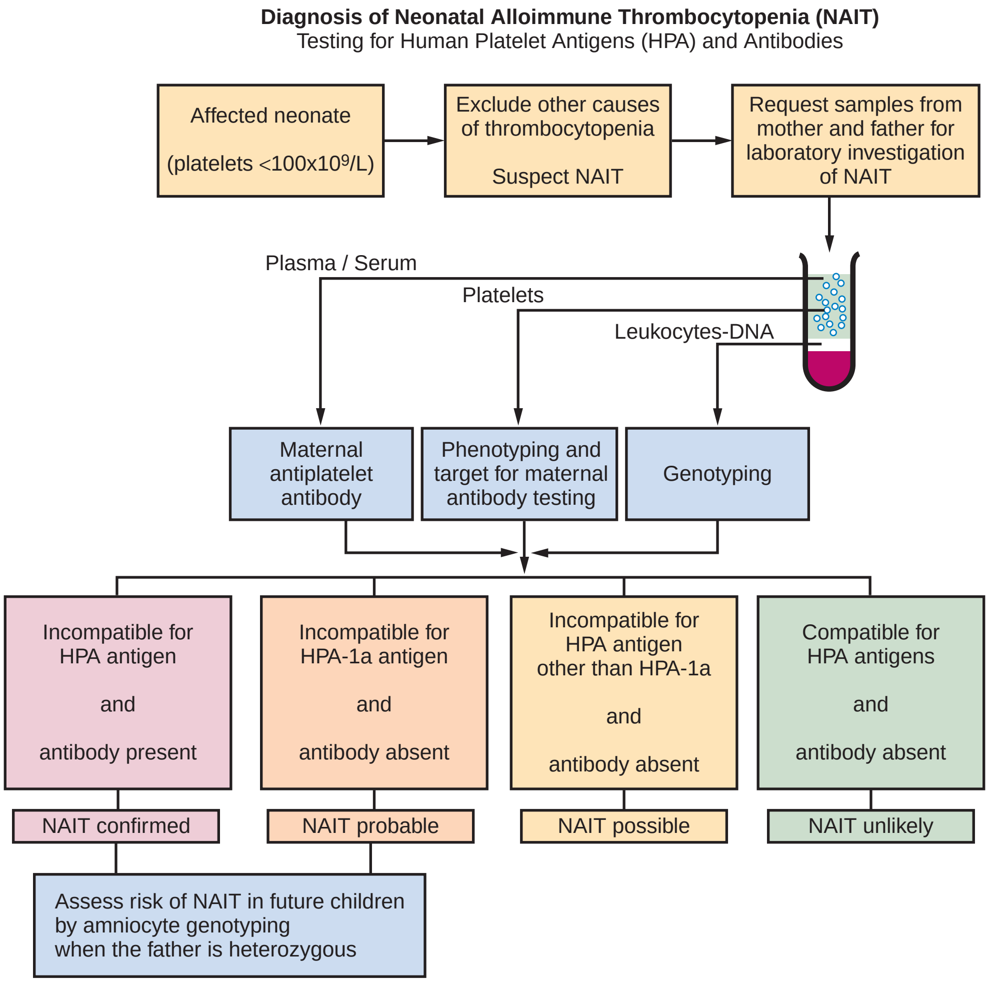
Laboratory Investigation of Suspected Neonatal Alloimmune Thrombocytopenia

The diagnosis of NAIT is established by documenting the presence of platelet-specific antigen incompatibility between mother and infant (or mother and father) and the presence of maternal antiplatelet alloantibodies directed against the incompatible human platelet antigen (HPA) (Fig. 129.3).[64] Diagnosis first requires allele-specific genotyping using polymerase chain reaction technology to identify a maternal-fetal (or maternal-paternal) antigenic mismatch. In the prenatal setting where fetal HPA status is unclear (e.g., paternal testing is unavailable, or if the father is heterozygous for the implicated antigen), chorionic villous sampling or amniocentesis may be pursued to establish fetal HPA status but are associated with procedure-related risks, including miscarriage. Noninvasive approaches using maternal cell-free DNA to establish fetal HPA status can also be used but may not be widely available.[65]

Serologic confirmation for the complete array of maternal alloantibodies is more difficult for two reasons. First, the technology is complex, and relatively few laboratories perform these tests. In general, most commercial assays detect platelet alloantibodies directed against only a limited number of antigens. This limitation necessitates the use of more specific assays, such as monoclonal antibody immobilization of platelet antigen assays (MAIPAs) or antigen capture assays; however, even these tests are limited by the shortage of monoclonal antibodies required to capture the different target proteins that express the alloantigens (e.g., HPA-15 on CD109). An alternative method uses radioimmunoprecipitation (RIP), which can detect all the known alloantibodies described to date. Second, up to 25% of HPA-1a–negative women with NAIT have no detectable antibodies using currently available laboratory methods. More recent studies have used surface plasmon resonance to identify alloantibodies in women suspected of having NAIT but who tested negative in conventional immunoassays. Low-affinity anti–HPA-1a antibodies were

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA VERSUS HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

NAIT can be viewed as the platelet equivalent of HDFN with some important differences: (1) maternal sensitization by fetal platelet antigens can occur early in the first trimester; (2) NAIT can affect first pregnancies; (3) women at risk for NAIT are not easily identifiable before sensitization and thus are not amenable to universal screening programs; and, (4) specific therapies to prevent platelet antigen sensitization are lacking (unlike HDFN due to anti-D, where Rh-immune globulin is available to prevent alloimmunization).



Diagnosis of Neonatal Alloimmune Thrombocytopenia (NAIT)
Testing for Human Platelet Antigens (HPA) and Antibodies
Affected neonate
(platelets <100x10⁹/L)
Exclude other causes of thrombocytopenia
Suspect NAIT
Request samples from mother and father for laboratory investigation of NAIT
Plasma / Serum
Platelets
Leukocytes-DNA
Maternal antiplatelet antibody
Phenotyping and target for maternal antibody testing
Genotyping
Incompatible for HPA antigen and antibody present
Incompatible for HPA-1a antigen and antibody absent
Incompatible for HPA antigen other than HPA-1a and antibody absent
Compatible for HPA antigens and antibody absent
NAIT confirmed
NAIT probable
NAIT possible
NAIT unlikely
Assess risk of NAIT in future children by amniocyte genotyping when the father is heterozygous

Figure 129.3 DIAGNOSTIC TESTING ALGORITHM FOR INVESTIGATION OF NEONATAL ALLOIMMUNE THROMBOCYTOPENIA AND MANAGEMENT RECOMMENDATIONS BASED ON RESULTS OF TESTING. This algorithm is currently used by the McMaster University Platelet Immunology Reference Laboratory, 2017. Maternal blood samples are tested for platelet antigens (phenotyping and polymerase chain reaction genotyping) and platelet alloantibodies. Amniocentesis and fetal genotyping are recommended when the father is known to be heterozygous for the incompatible antigen. *HPA*, Human platelet antigen; *NAIT*, neonatal alloimmune thrombocytopenia. *(Modified from Arnold DM, Smith JW, Kelton JG. Diagnosis and management of neonatal alloimmune thrombocytopenia. Transfus Med Rev. 2008;22:255, with permission.)*

detected in some, suggesting that standard immunoassays may be limited in their capacity to detect such antibodies.[66] In addition, low-incidence platelet-specific alloantigens expressed on platelets only from the paternal lineage may account for fetomaternal incompatibility. Detection of alloantibodies in these cases requires that maternal serum be tested against paternal platelets whenever possible.

The most common platelet alloantigen implicated in NAIT is HPA-1a. This important alloantigen is defined by a leucine (HPA-1a) to proline (HPA-1b) substitution at amino acid 33 on GPIIIa. Maternal incompatibility to HPA-1a is implicated in more than 80% of patients with NAIT. These women lack the common HPA-1a antigen (i.e., their genotype is HPA-1bb), and during pregnancy they are immunized with fetal HPA-1a antigen inherited from the father. Other commonly implicated antigens are HPA-5a5b on GPIa/IIa and HPA-15a15b on the glycosylphosphatidylinositol-anchored protein CD109. Only 6 of the 28 platelet antigen systems have been defined by maternal alloantibodies against both alleles; these include the HPA 1, 2, 3, 4, 5, and 15 systems. There are several other low-frequency alleles, the majority of which are expressed on platelet GPIIb/IIIa and are usually found within a single family. Although maternal immunization to low-frequency antigens is implicated in some cases of NAIT, these antigens account for a minority of the NAIT cases that remain unresolved after investigation for common HPA antigens.[67] Frequently, discrepancies in human leukocyte antigen (HLA) and ABO, which are also expressed on platelets, are found during the course of investigations for NAIT; however, their significance is uncertain. A database of genetically confirmed alloantigens is maintained by the European Bioinformatics Institute (http://www.ebi.ac.uk).

Management

Postnatal Management of Infants After Delivery

When NAIT is suspected, treatment should be initiated before confirmatory test results are available if thrombocytopenia is severe (platelet count <30 × 10^9/L) or if there is evidence of bleeding. It is important to appreciate that thrombocytopenia at birth can worsen over the next few days among patients with NAIT. Platelet transfusions can be administered to increase neonatal platelet counts. HPA alloantigen-compatible platelets are more effective than random donor platelets in achieving higher posttransfusion platelet counts, but if HPA antigen-selected platelets are unavailable, random donor platelets can still be administered because they frequently produce adequate platelet count increments.[68] High-dose IVIg (1 to 2 g/kg) may be considered as an adjunct to platelet transfusion. Current guidelines recommend that all neonates suspected of NAIT undergo routine cranial ultrasound within 24 hours of delivery.

Antenatal Management of Mothers in Subsequent Pregnancies

Women with a previously affected infant with NAIT are at high risk of having another affected infant, and thus careful management during subsequent pregnancies is required. Paternal HPA genotyping should be performed for the antigen(s) implicated in previous NAIT case(s), and in cases of paternal antigen heterozygosity or if antigen status is unknown/unavailable, fetal antigenic testing can be performed by amniocentesis or cell-free DNA to determine if the fetus is at risk and whether treatment is required.

Antenatal treatment options for at-risk mothers during subsequent pregnancies range from careful observation, IVIg with or without corticosteroids, to fetal blood sampling (FBS) and intrauterine platelet transfusion (IUPT). Invasive strategies such as FBS and IUPT are associated with heightened rates of complications, including fetal death and premature labor without benefits in clinical outcomes[69]; therefore a noninvasive approach is recommended. Mainstay antenatal therapy for women with a previously affected infant is high-dose IVIg (1 to 2 g/kg) administered weekly throughout pregnancy. The optimal timing at which antenatal IVIg should start is 12 to 16 weeks for women with a child affected by fetal/neonatal ICH and between 20 and 22 weeks for women without an ICH affected fetus/neonate.[70] A systematic review summarizing the results of four randomized trials and 22 observational studies found no consistent evidence supporting the addition of corticosteroids.[69] Corticosteroids (prednisone) are given at some centers in combination with IVIg to mothers at high risk, such as those with a previously affected infant with ICH or severe thrombocytopenia, or if the response to IVIg is suboptimal. Dexamethasone has an associated risk with oligohydramnios and is not recommended in current guidelines.[70]

Antenatal Fetal Monitoring of At-Risk Fetuses

Serial ultrasonography is indicated for fetal surveillance. Ultrasound provides a simple, noninvasive method for identifying fetal bleeds at early stages. FBS by percutaneous cannulation of the umbilical or intrahepatic vein with or without IUPT was associated with an 11% rate of complications in a systematic review (54 complications in 497 treated pregnancies), with 26% leading to fetal loss.[69] Furthermore, a platelet transfusion protocol based on the detection of fetal thrombocytopenia would necessitate frequent FBS procedures because of the short (7-day) lifespan of transfused platelets. As such, routine FBS with or without IUPT is not recommended. Among HPA-1a immunized women, serial measurement of anti-HPA-1a antibody levels may be useful to predict the degree of fetal thrombocytopenia.[71]

Mode of Delivery

There is no evidence that planned cesarean section is safer than uncomplicated vaginal delivery for infants with NAIT. A planned delivery is important to ensure that personnel and resources, including antigen-compatible platelet transfusions, are readily available. Invasive fetal procedures (scalp blood sampling and electrodes) or assisted deliveries (forceps, vacuum) should be avoided if the fetal platelet count is unknown.

Population Screening for Neonatal Alloimmune Thrombocytopenia

Universal NAIT screening programs for all pregnant women are challenging because of the difficulty in early identification of at-risk women, the low prevalence of NAIT, and the lack of specific and proven treatments for the prevention of alloimmunization. Screening algorithms also must account for the large difference between the number of women lacking an antigen and the number who develop NAIT; about 2% of women will be identified as HPA-1bb, whereas only 1 in 20 of these will have an affected child because of HPA-1a immunization.[72] As such, universal screening programs are not currently available, but there are ongoing research initiatives targeting the development of prophylactic therapies to prevent HPA-1a alloimmunization.[73] However, sisters of women with a history of NAIT should undergo screening because they are likely to possess similar HPA genotypes. HLA DRB3*01:01 typing may be useful because its absence in non–HPA-1a mothers without an affected fetus/neonate and without HPA-1a antibodies confers a low risk of alloimmunization.[74]

POSTTRANSFUSION PURPURA

PTP is a rare thrombocytopenic syndrome that is provoked by an immune-mediated reaction against HPAs, most frequently HPA-1a. PTP presents 5 to 10 days following exposure to platelets or platelet antigenic material in blood transfusions with profound thrombocytopenia and clinically significant bleeding.

Epidemiology

PTP is rare with an unknown incidence; however, estimates place incidence around 1 to 2 per 100,000 transfusions. Data from the Serious Hazards of Transfusion (SHOT) surveillance program from the United Kingdom reveal decreased incidence of PTP over the past decade (Fig. 129.4).[75] This decrease may reflect universal leukoreduction, which was implemented in the United Kingdom in 1999. The average annual incidences of PTP in the years preceding 1996–99 and following the implementation of universal leukoreduction between 2000 and 2005 were 10.3 and 2.3 cases per year, respectively. Since the implementation of universal leukoreduction, there has also been a shift from RBCs to platelets as the inciting transfusion event, which may be attributable to the reduction in platelet contamination of red cell products with leukoreduction methods. One study estimated that the frequency of PTP corresponds to 1.8 per 100,000 transfusions.[76] In this study, platelet containing transfusions posed a significantly higher risk than RBC transfusions.

The majority of PTP cases are reported in women, the majority of whom had a history of pregnancy; 52/53 confirmed cases of PTP were women according to SHOT data. In a report of 61 patients, the sensitizing event among women was pregnancy alone in 58%, pregnancy and/or transfusion in 34%, and transfusion alone in 7.5%. Males had associated transfusion histories in 55%, with some having no known exposure. PTP has not been reported in children.

Clinical Presentation

PTP presents with severe thrombocytopenia (platelets $<10 \times 10^9$/L) and bleeding, which may include petechiae, purpura, mucosal hemorrhage, hematuria, and rarely ICH. The platelet drop can occur over 24 hours. The thrombocytopenia is often refractory to platelet transfusions even with antigen-negative platelets. Mortality because of severe thrombocytopenia and bleeding has been estimated to be 5% to 20%. The thrombocytopenia occurs 5 to 10 days after blood transfusion and typically resolves within weeks but occasionally can be prolonged and severe and persist for months. Other causes of thrombocytopenia with similar clinical presentation include primary ITP, drug-induced ITP, sepsis, disseminated intravascular coagulation, and thrombotic thrombocytopenic purpura; however, association with transfusion and bleeding severity suggests a diagnosis of PTP. Patients with PTP may present with features that overlap with heparin-induced thrombocytopenia (HIT), and positive HIT testing in the context of anti–HPA antibodies has been reported; however, thrombocytopenia is

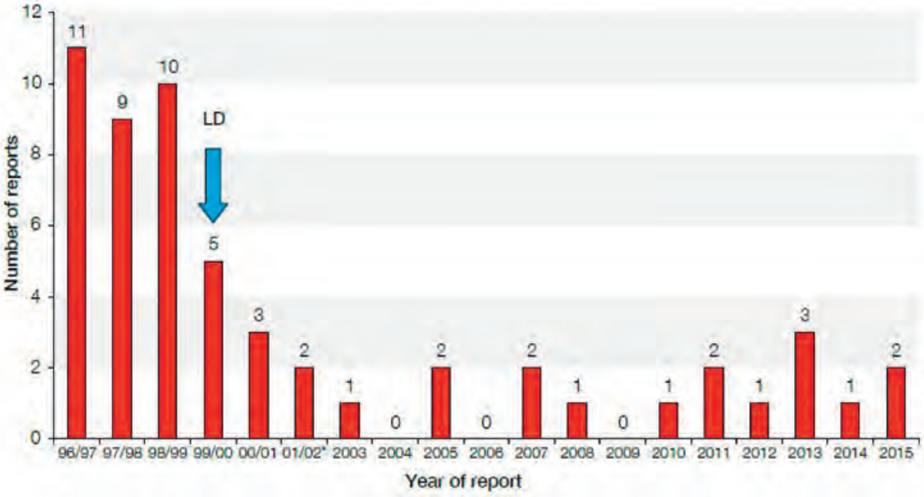


Figure 129.4 CONFIRMED CASES OF POSTTRANSFUSION PURPURA REPORTED BY THE UK SERIOUS HAZARDS OF TRANSFUSION (SHOT) SURVEILLANCE PROGRAM. Universal leukoreduction began in the United Kingdom in late 1999 and coincided with a decrease in new cases of posttransfusion purpura. *(From* www.shotuk.org.*)*

CLINICAL PRESENTATION OF POSTTRANSFUSION PURPURA

On postoperative day 8 after spinal surgery, a 63-year-old woman has a platelet count of 3×10^9/L. During the operation, she received 3 units of non–leuko-reduced packed RBCs because of intraoperative bleeding. She is receiving intravenous ampicillin and dalteparin thromboprophylaxis. On physical examination, she has extensive oral mucosal purpura and petechiae on both lower extremities. HIT testing results (anti-PF4/heparin enzyme-linked immunosorbent assay and serotonin release assay) are negative (see Chapter 130). The ampicillin is stopped, and she is treated with IVIg (2 g/kg) and platelet transfusions. Three days later, the platelet count is 4×10^9/L, and the patient develops melena. The presumed diagnosis is posttransfusion purpura; therefore HPA-1a–negative platelets and high-dose parenteral corticosteroids are administered, and daily plasma exchange is initiated. One week later, the thrombocytopenia and bleeding symptoms resolve. Platelet antibody testing reveals the presence of anti–HPA-1a antibodies.

typically less severe with HIT, and bleeding is rare (see Chapter 131). (See box on Clinical Presentation of Posttransfusion Purpura.)

Diagnosis

Diagnosis of PTP is confirmed by presence of platelet-specific alloantibodies. Most patients with PTP lack the common HPA-1a platelet antigen and are homozygous for HPA-1b. These patients develop anti-HPA 1a antibodies from sensitizing events such as previous pregnancies or transfusions. Anti–HPA 1a antibodies may persist for many years in these patients. In addition, platelet antibodies with specificities other than HPA-1a may also be found.[77] Direct and indirect methods for identifying platelet-specific antibodies can be used.[78]

Pathophysiology

PTP is mediated by an anamnestic antibody response. Most patients who develop PTP were exposed to a sensitizing event against platelet antigens that are absent on the patient's platelets. PTP occurs after reexposure to the same antigen when present in transfused blood products. The most common scenario involves a middle-aged or older multiparous woman who is HPA 1b-1b.[78]

Platelets contain abundant amounts of GPIIb/IIIa (see Chapter 123); thus even small numbers of platelets or platelet microparticles contained within RBC concentrates can be immunogenic and can lead to the development of PTP. Genotypic analyses have shown that HLA-II alleles DRβ3*0101 and DQβ1*0201 are commonly associated with this disorder. Similar to NAIT, the frequency of immunization depends on platelet alloantigen discrepancy plus the presence of certain immune response genes.

The most intriguing feature of PTP is that the patient's own antigen-compatible platelets are destroyed. Furthermore, platelet reactive antibodies can be eluted from both antigen-positive and antigen-negative platelets. Although the mechanism is still poorly understood, theories to explain this "innocent bystander" phenomenon include immune complex formation, passive antigen adsorption, and autoantibody formation.

Immune complexes can form if the anti–HPA-1a antibodies bind soluble antigen. Alternatively, platelet alloantigens contained within the transfused blood product may be passively adsorbed onto autologous platelets, converting them from antigen negative to antigen positive and rendering them targets for immune destruction. Immune complexes may then bind to platelets through Fc receptors, causing platelet destruction. Anti–HPA-1a antibodies have been shown to induce platelet activation through release of platelet-derived RANTES (regulated on activation, normal, T-cell expressed and secreted), a proinflammatory and immunomodulatory chemokine involved in multiple immunologic processes, including Ig synthesis and regulation of Th1/Th2 cytokine homeostasis. In some patients with PTP, the alloantibodies have been shown to interfere with cell-fibrinogen interaction, thereby increasing the risk of bleeding.

The stimulation of specific anti–HPA alloantibodies could in turn initiate the formation of platelet-reactive *autoantibodies*. Production of pan-reactive antibodies has been shown to correspond with the period of greatest thrombocytopenia. Serologic analyses of PTP cases demonstrated the presence of reactive IgG and IgM antibodies against GPIIb/IIIa, GPIX, and GPIa/IIa; however, only HPA-specific IgG antibodies persisted.[79] The presence of autoantibodies can help to explain the destruction of both donor and recipient platelets.

Management

Treatment of PTP should be initiated even before serologic test results for anti–HPA-antigens are available. The primary goal of treatment is to abbreviate the period of severe thrombocytopenia and minimize the risk of bleeding. Multiple treatments are often administered simultaneously or in rapid succession because of potential severity of sequelae.

Patients with PTP require admission to hospital for close observation, supportive treatments, and rapid management of bleeding symptoms should they occur. Nonessential transfusions should be discontinued. The mainstay of therapy is high-dose IVIg, which is followed by a platelet count increase after 3 to 4 days.[80] High-dose corticosteroids have also been tried as a means of inhibiting RES phagocytosis and reducing IgG synthesis. Patients with bleeding should be transfused with HPA-compatible platelets. While awaiting the results of antigen typing, HPA-1a–negative platelet transfusions can be administered to reduce further antibody production. Patients with PTP may be at increased risk of transfusion reactions such as fever, dyspnea, and allergic reactions. Plasma exchange should be considered in patients who do not respond to IVIg and corticosteroids.

A review of the literature supported use of IVIg (1B) and plasma exchange (2B) in management of PTP; and use of leukocyte reduction (2A), avoidance of unnecessary transfusion (2C), and if transfusion is required, HPA-compatible or washed cellular products (2C)[81] as preventative measures.

CHAPTER **130**

THROMBOCYTOPENIA CAUSED BY HYPERSPLENISM, PLATELET DESTRUCTION, OR SURGERY/HEMODILUTION

Theodore E. Warkentin

Thrombocytopenia is defined as a platelet count below the lower limit of the normal range ($\approx 150 \times 10^9$/L). Sometimes, an expanded definition of thrombocytopenia is appropriate. For example, an abrupt drop in the platelet count can signify the onset of a disorder such as heparin-induced thrombocytopenia (HIT) or bacteremia even if the platelet count remains above 150×10^9/L.[1] This is especially relevant in the second or third week after surgery because patients usually have platelet counts that peak at levels two to three times higher than their usual preoperative value (postoperative thrombocytosis).[2]

In the clinical evaluation of a patient with thrombocytopenia, three questions must be asked. First, could the patient have pseudothrombocytopenia? Second, what is the most likely explanation for the thrombocytopenia? Third, what are the risks posed by the causative disorder and the severity of the thrombocytopenia? For example, severe thrombocytopenia caused by drug-dependent antibodies or platelet-reactive autoantibodies is often associated with bleeding. By contrast, thrombocytopenia caused by HIT antibodies or attributable to disseminated intravascular coagulation (DIC) secondary to adenocarcinoma is associated with thrombosis (see Chapters 131 and 137, respectively). Often, the underlying cause of the thrombocytopenia (e.g., bacteremia, cancer, cirrhosis), rather than the thrombocytopenia itself, poses the greater risk.

Thrombocytopenia can be caused by any of five general mechanisms: (1) platelet underproduction, (2) increased platelet destruction, (3) increased platelet consumption, (4) platelet sequestration, and (5) hemodilution. Platelet underproduction usually occurs in association with underproduction of other blood cell lines, which results in bicytopenia or pancytopenia. Thrombocytopenia caused by increased platelet destruction develops when immune-mediated mechanisms, most often platelet-reactive antibodies, cause the rate of platelet loss to surpass the ability of the bone marrow (BM) to produce platelets. In contrast, increased platelet consumption refers to pathological enhancement of physiological mechanisms, with resulting increased platelet loss. Examples include increased thrombin-mediated platelet consumption (DIC) and increased platelet-von Willebrand factor interactions (thrombotic microangiopathy [TMA]). Table 130.1 lists some causes of platelet destruction and consumption. Thrombocytopenia from platelet sequestration is caused by platelet redistribution from the circulation into an enlarged splenic vascular bed. Hemodilution is characterized by a decreased number of platelets, as well as red blood cells (RBCs) and white blood cells (WBCs) as a result of the administration of colloid, crystalloid, or platelet-poor blood products.

Sometimes, pathophysiological mechanisms overlap. For example, immune HIT is caused by antibodies (destruction) that directly cause platelet activation and that also trigger DIC (consumption). Advanced liver disease can feature severe thrombocytopenia as a result of hypersplenism (sequestration), hyperfibrinolysis (consumption), and decreased thrombopoietin production (underproduction).

In the postoperative period, platelet count changes reflect several processes, including initial hemodilution (immediate platelet count decrease) and increased platelet consumption (first 2 to 4 days), at which point the platelet count begins to rise because of increased platelet production. When the platelet count reaches its postoperative peak—usually about 14 days after surgery—platelet production decreases somewhat, and the platelet count returns to baseline (Fig. 130.1).[2]

APPROACH TO PATIENTS WITH THROMBOCYTOPENIA

History and Physical Examination

Certain information should be ascertained, including (1) the location and severity of bleeding (if any); (2) the temporal profile of the hemostatic defect (acute, chronic, or relapsing), particularly the temporal relationship with potential proximate triggers (e.g., new drugs, recent infection); (3) the presence of symptoms of a secondary illness, such as a neoplasm, infection, or an autoimmune disorder such as systemic lupus erythematosus (SLE); (4) history of recent medication use, alcohol ingestion, or transfusion; (5) presence of risk factors for certain infections, particularly human immunodeficiency virus (HIV) infection or viral hepatitis; and (6) family history of thrombocytopenia.

As part of the physical examination, evidence of hemostatic impairment should be sought, as well as secondary causes of thrombocytopenia. The signs of platelet-related bleeding include petechiae and purpura. Petechiae typically occur in the dependent regions of the body or on traumatized areas. Spontaneous mucous membrane bleeding (wet purpura), epistaxis, hematuria, and gastrointestinal bleeding indicate a more serious hemostatic defect. Although petechiae are common in patients whose platelet counts are less than 10 to 20×10^9/L, most patients with platelet counts over 50×10^9/L have no signs of hemostatic impairment. The physical examination may provide an explanation for the thrombocytopenia. For example, enlarged lymph nodes may indicate a viral infection, such as infectious mononucleosis or HIV infection, or a neoplastic process. An enlarged spleen raises the possibility of hypersplenism.

Timing of Onset and Severity of Thrombocytopenia

Many thrombocytopenic disorders, particularly those involving an immune pathogenesis, exhibit characteristic temporal features that can aid in the diagnosis. For example, if the platelet count begins to fall 5 to 10 days (median, 6 to 7 days) after starting a new drug or after a blood transfusion and reaches a nadir of less than 20×10^9/L a few days later, the diagnosis of drug-induced immune thrombocytopenia (D-ITP) or posttransfusion purpura (PTP), respectively, should be considered (Fig. 130.2).[3] Patients with these disorders typically have mucocutaneous bleeding and are at risk for fatal intracranial hemorrhage.

A similar temporal profile is also characteristic of typical-onset HIT (see Chapter 130), although in that disorder the platelet count falls below 20×10^9/L in only 5% to 10% of affected patients (see Fig. 130.2); in approximately 80% to 90% of patients, the platelet count nadir ranges from 20 to 150×10^9/L; and in the remainder, the platelet count nadir never falls below 150×10^9/L despite a large reduction in the platelet count.[4] When the platelet count falls abruptly after drug administration, the possibility of rapid-onset thrombocytopenia caused by preexisting drug-dependent antibodies should be considered, as is well described with HIT. Indeed, so-called rapid-onset HIT is the presenting feature of this adverse drug reaction in 25% to 30% of cases.[5] Rapid-onset thrombocytopenia is also a feature of glycoprotein (GP) IIb/IIIa (αIIbβ3) antagonist-induced ITP (see Chapter 129).[6]

TABLE 130.1 Mechanisms of Platelet Destruction or Consumption

Type of Thrombocytopenia	Specific Example(s)
Platelet Destruction (Immune-Mediated)	
Autoantibody-mediated platelet destruction by RES	Primary and secondary idiopathic (immune) ITP
Alloantibody-mediated platelet destruction by RES	NAIT, PTP, PAT; alloimmune platelet transfusion refractoriness
Drug-dependent, antibody-mediated platelet destruction by RES	Drug-induced immune ITP (e.g., quinine, vancomycin)
Platelet activation by binding of IgG Fc of drug-dependent IgG to platelet FcγIIa receptors	Heparin-induced thrombocytopenia (HIT)[a]; protamine (heparin)-induced thrombocytopenia (PHIT)[a]
Platelet Consumption (Pathologically Enhanced Physiological Mechanisms)	
Platelet consumption through platelet activation by thrombin or proinflammatory cytokines	DIC; septicemia or systemic inflammatory response syndromes; HIT[a], PHIT[a]
Hyperfibrinolysis	Disorders of hyperfibrinolysis (e.g., certain malignancies, advanced liver disease) include element of platelet consumption
Platelet consumption via ingestion by macrophages (hemophagocytosis)	Infections, certain malignant lymphoproliferative disorders
Platelet consumption through platelet interactions with altered vWF[c]	TMA disorders, e.g., iTTP,[b] HUS
Platelet losses on artificial surfaces	CPB, use of intravascular catheters
Decreased platelet survival associated with cardiovascular diseases	Congenital and acquired heart disease, cardiomyopathy, pulmonary embolism

CPB, Cardiopulmonary bypass surgery; *DIC*, disseminated intravascular coagulation; *HIT*, heparin-induced thrombocytopenia; *PHIT*, protamine (heparin) induced thrombocytopenia; *HUS*, hemolytic uremic syndrome; *IgG*, immunoglobulin G; *ITP*, idiopathic (immune) thrombocytopenic purpura; *iTTP*, immune-mediated thrombotic thrombocytopenic purpura; *NAIT*, neonatal alloimmune thrombocytopenia; *PAT*, passive alloimmune thrombocytopenia; *PTP*, posttransfusion purpura; RES, reticuloendothelial system; *TMA*, thrombotic microangiopathy; *VWF*, von Willebrand factor.

[a] HIT and PHIT have overlapping features of antibody-mediated platelet activation (destruction) and DIC (consumption).

[b] Although platelet destruction is not directly caused by antibodies, immune mechanisms can explain enhanced VWF-platelet interactions (e.g., autoimmune clearance of VWF-cleaving metalloprotease, associated with iTTP).

Occasionally, thrombocytopenia worsens in the first few days after surgery; this can occur with multiorgan system failure (e.g., cardiogenic or septic shock, with lactic acidemia) (see Fig. 130.2). If the patient develops concomitant DIC and hypotension, there is a high risk for ischemic limb injury secondary to microvascular thrombosis ("symmetric peripheral gangrene"), especially if the patient has "shock liver" (acute ischemic hepatitis), which is a risk factor for severe depletion of protein C and antithrombin, important endogenous anticoagulants (see Chapter 125).[7,8] Another potential contributory factor for severe natural anticoagulant depletion and risk for limb gangrene in susceptible patients is colloid transfusion (albumin, high-dose IVIG), which lacks coagulation factors including protein C and antithrombin.[9] If the platelet count falls to very low levels and is accompanied by microangiopathic hemolysis, the possibility of postoperative thrombotic thrombocytopenic purpura (TTP) should be considered (see Chapter 132).[10]

Rarely, abrupt thrombocytopenia, with or without complicating thrombosis, can occur in post-cardiac or vascular surgery patients following protamine administration (to reverse intraoperative heparin anticoagulation).[11] This disorder is caused by platelet-activating anti-protamine (heparin) antibodies ("protamine [heparin]-induced thrombocytopenia"). Because these antibodies are transient, at-risk patients include those with recent exposure to both heparin and protamine, such as patients who previously underwent cardiac or vascular surgery (in the recent past) or who may have received preoperative unfractionated or low-molecular-weight heparin while at the same time receiving protamine-containing insulin products.

Mild to moderate platelet count decreases that occur soon after transfusion of blood products are common and can be explained by hemodilution; however, a marked platelet count fall after transfusion may be the result of passive alloimmune thrombocytopenia (PAT)[12,13] or sepsis because of contaminated blood products (see Fig. 130.2).

Other characteristic temporal features of thrombocytopenia include postenterohemorrhagic *Escherichia coli*–associated hemolytic uremic syndrome (HUS); thrombocytopenia and microangiopathic hemolysis that begin approximately 1 week after a prodromal diarrheal illness; and fungemia-associated thrombocytopenia (onset, 1 to 3 weeks after complex illness involving indwelling catheters and broad-spectrum antibiotic use). In contrast, thrombocytopenia of insidious onset that progresses over several years suggests chronic liver disease, with evolution to portal hypertension and associated splenomegaly (e.g., cirrhosis secondary to alcohol or hepatitis C) or a slowly progressive BM disorder (e.g., myelodysplasia).

Laboratory Evaluation

Laboratory evaluation of patients with thrombocytopenia includes evaluation of the complete blood count (CBC), examination of the peripheral blood film, and obtaining relevant ancillary studies, which sometimes includes BM aspirate/biopsy.

The blood film is examined to exclude pseudothrombocytopenia, which is characterized by in vitro platelet clumping. This phenomenon, which is evident in approximately 1 in 1000 blood samples, is most often caused by naturally occurring GPIIb/IIIa-reactive autoantibodies that induce aggregation of platelets in the presence of the calcium-chelating anticoagulant ethylenediamine tetraacetic acid (EDTA). Because the platelet aggregates are not counted by the electronic particle counter, the automated platelet count appears falsely low. The correct platelet count usually can be determined by collecting the blood into sodium citrate or heparin or by performing the count on nonanticoagulated finger prick samples; maintaining the blood sample at 37°C often attenuates platelet clumping. EDTA-dependent pseudothrombocytopenia has no pathologic significance other than potentially placing a patient in jeopardy for inappropriate treatment for thrombocytopenia that does not exist. A much less common (1 in 10,000 blood samples) antibody-mediated pseudothrombocytopenic disorder is platelet satellitism, in which rosette-like clusters of platelets surround the neutrophils. This entity is produced by immunoglobulin G (IgG) antibodies that recognize EDTA-induced cryptic epitopes on both platelet GPIIb/IIIa and neutrophil FcγIII receptors.

BM examination can be helpful for platelet production assessment, particularly if megakaryocytes are reduced or abnormal in appearance. Examination of the BM can be diagnostic in some disorders (e.g., leukemia, metastatic tumor, Gaucher disease, megaloblastic anemia).

Besides the CBC, commonly performed blood tests to evaluate thrombocytopenia include: prothrombin time/international normalized ratio (PT/INR), partial thromboplastin time (PTT), fibrinogen, D-dimer (screening tests for DIC), serum enzyme levels such as lactic dehydrogenase (LDH), alanine aminotransferase (ALT), aspartate aminotransferase (AST), creatine phosphokinase (CPK) (evaluation of hemolysis, shock liver, muscle injury), blood cultures (bacteremia, fungemia). More specific assays appropriate in selected patients include testing for HIT or non-HIT drug-dependent platelet-reactive antibodies (e.g., using

Figure 130.1 POSTSURGERY PLATELET COUNT CHANGES. Initial platelet count declines result from hemodilution and increased platelet consumption, with the platelet count nadir occurring between postoperative days 1 to 4 (median, day 2). There is constitutive production of thrombopoietin (TPO) by the liver. TPO binds to platelets and megakaryocytes via a specific receptor (c-Mpl, not shown), and receptor-bound TPO is removed from the circulation and degraded. The level of circulating TPO is thus inversely related to the mass of platelets and megakaryocytes. In early postsurgery thrombocytopenia, fewer TPO binding sites are available, resulting in high free TPO levels, which stimulate megakaryocyte proliferation and differentiation and lead to increased platelet production. With subsequent thrombocytosis, the high platelet mass acts as a "sink" for removing TPO, with decreased stimulus for platelet production. Thus after acute postsurgery thrombocytopenia, TPO levels rise about twofold, leading to increased platelet production that begins on days 2 to 4, with resulting thrombocytosis that generally peaks at approximately day 14 (postoperative thrombocytosis) and returns to baseline by about day 21. *(Reprinted, with modifications, with permission, from Arnold DM, Warkentin TE. Thrombocytopenia and thrombocytosis. In: Wilson WC, Grande CM, Hoyt DB, eds. Trauma: Critical Care. Vol. 2. New York: Informa Healthcare; 2007:983.)*

the monoclonal antibody immobilization of platelet antigens [MAIPA] test), platelet-reactive alloantibodies, antiphospholipid antibodies (nonspecific inhibitor, anti-cardiolipin antibodies, anti-β_2-glycoprotein 1 antibodies), quantitative immunoglobulin determination and serum protein electrophoresis, viral serology (HIV, hepatitis C, etc.), tests for hemolysis (direct Coombs test, haptoglobin levels, etc.).

In exceptional circumstances, when the mechanism of chronic thrombocytopenia is unclear, an autologous platelet survival study using ^{111}In-labeled platelets may be informative. Three patterns can be seen: (1) normal platelet survival and recovery (underproduction), (2) marked reduction in the platelet life span (increased destruction or consumption), and (3) reduced recovery but a normal or near-normal life span (sequestration). However, platelet survival studies are rarely performed.

Therapy

The risk of bleeding in patients with thrombocytopenia can be reduced by avoiding drugs that impair hemostasis (e.g., alcohol, antiplatelet agents, anticoagulants) and invasive procedures (e.g., intramuscular injections). If drug-induced thrombocytopenia is suspected, as many medications as possible, especially those started within the preceding 5 to 14 days, should be stopped. Life-threatening bleeding episodes should be treated with platelet transfusion regardless of the mechanism of the thrombocytopenia.

The underlying cause and anticipated natural history of the thrombocytopenic disorder influence the decision about prophylactic platelet transfusion. As a rule, patients with chronic thrombocytopenic disorders characterized by increased platelet destruction (e.g., chronic immune thrombocytopenia [ITP]) or chronic underproduction (e.g., aplastic anemia or myelodysplasia) can tolerate long periods of severe thrombocytopenia without major bleeding (see Chapter 113). In addition, prophylactic platelet transfusions can trigger alloimmunization against human leukocyte antigen (HLA) or platelet antigens, thereby jeopardizing future therapeutic platelet transfusions. Consequently, prophylactic platelet transfusions are seldom indicated for such patients except when they are at risk of bleeding because of trauma or major surgery. When platelets are given, the platelet count should be maintained above 50×10^9/L ($>100\times10^9$/L, if possible, for central nervous system procedures). Invasive procedures such as thoracentesis, paracentesis, and liver biopsy are not usually associated with excess bleeding if the platelet count is greater than 50×10^9/L.

Prophylactic platelet transfusions should not be given to patients with strongly suspected or confirmed HIT, TTP, HUS, and, possibly, DIC, because they may exacerbate platelet-mediated thrombotic complications, and, particularly with HIT, mucocutaneous bleeding is uncommon. However, bleeding from severe thrombocytopenia, or other patient-specific considerations, may justify platelet transfusion even in these disorders.

ANATOMY AND PHYSIOLOGY

The Spleen: Anatomy and Function

The spleen is a small, well-perfused organ that receives about 5% of the total cardiac output. In adults, the spleen weighs between 150 and 200 g and measures approximately 11 cm in length.

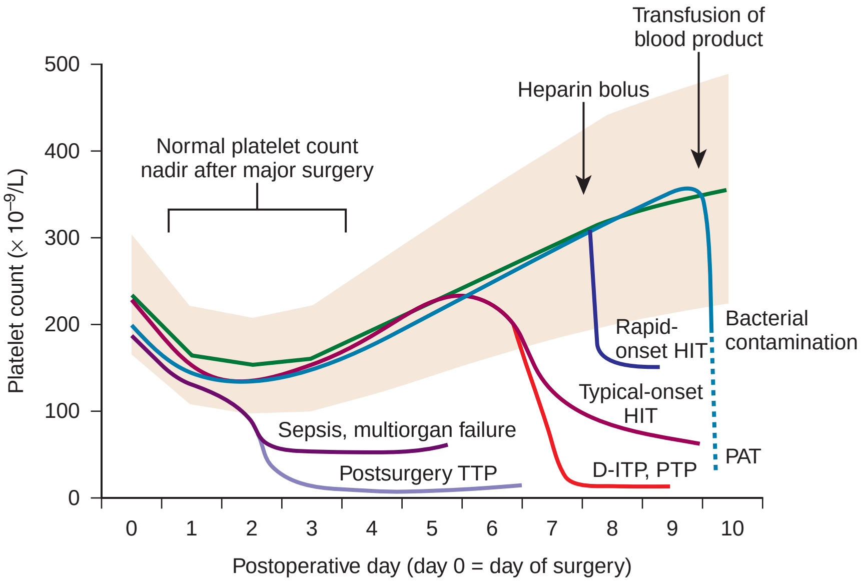

Figure 130.2 TIMING OF ONSET AND SEVERITY OF THROMBOCYTOPENIA: IMPLICATIONS FOR DIFFERENTIAL DIAGNOSIS. The usual postoperative platelet count nadir is seen between postoperative days 1 to 3 (inclusive). Early and progressive platelet count declines often reflect severe postoperative complications such as sepsis and multiorgan failure; severe thrombocytopenia plus microangiopathic hemolysis can (rarely) indicate postsurgery thrombotic thrombocytopenic purpura. Thrombocytopenic disorders that begin approximately 1 week after surgery are often immune mediated: moderate thrombocytopenia can indicate heparin-induced thrombocytopenia (HIT), both "typical onset" or (if heparin is not being given) "delayed onset"; very severe thrombocytopenia can indicate drug-induced immune thrombocytopenia (D-ITP) or (rarely) posttransfusion purpura. An abrupt decline in platelet count after receiving a heparin bolus in a patient who has received heparin within the past 7 to 100 days can indicate "rapid-onset" HIT; thrombocytopenia that begins abruptly after transfusion of a blood product can indicate sepsis from bacterial contamination or (rarely) passive alloimmune thrombocytopenia caused by transfusion of platelet-reactive alloantibodies. *D-ITP*, Drug-induced immune thrombocytopenia; *HIT*, heparin-induced thrombocytopenia; *PAT*, passive alloimmune thrombocytopenia; *PTP*, posttransfusion purpura; *TTP*, thrombotic thrombocytopenic purpura. *(Reprinted, with permission, from Greinacher A, Warkentin TE. Acquired non-immune thrombocytopenia. In: Marder VJ, Aird WC, Bennett JS, et al., eds. Hemostasis and Thrombosis: Basic Principles and Clinical Practice. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2013:796.)*

The anatomy of the spleen is uniquely suited for its function; progressive branching of the splenic artery into trabecular and central arteries helps separate the plasma from the cellular elements (see Chapter 156). The central arteries arise perpendicularly from the trabecular arteries and skim the plasma layer from the cells. Soluble antigens in the plasma are delivered to the white pulp, where phagocytic cells process them and antibody production is initiated.

A cell-rich, hemoconcentrated fraction of the blood is delivered to the red pulp. Some of this blood flows directly to the splenic veins (the closed system), but most moves into the splenic cords (the open system). Here, the cellular elements percolate through a meshwork of reticulum fibers, reticuloendothelial cells, and supporting cells to reach the splenic sinuses. The cells enter the sinuses by passing through narrow fenestrations in the basement membrane of the endothelial cells lining the sinuses. The blood exits through the splenic vein into the portal system. Because the veins in the portal system lack valves, any increase in portal pressure is transmitted to the splenic microcirculation.

The spleen plays many important roles. It is the largest lymphoid organ in the body and contributes to host defense by clearing microorganisms and antibody-coated cells. The spleen is also important for antibody synthesis, especially antibodies directed against soluble antigens. The filtering function of the spleen includes (1) culling (removal of damaged or senescent cells and bacteria), (2) pitting (removal of RBC inclusion bodies or parasites), and (3) remodeling (reticulocyte sequestration and maturation). The spleen also serves as a reservoir of platelets (accommodating about one-third of the platelet mass in normal individuals). By contrast, the human spleen contains less than 2% of the total RBC mass, although in some animals (dogs and cats), the spleen is a much more important RBC reservoir.

Physiologic Platelet Sequestration

Radiolabeled platelet studies have shown that approximately 30% of the total platelet mass exists as a freely exchangeable pool in the spleen. Because the normal platelet life span is 9 to 10 days, platelets spend approximately one-third of their lives, or 3 days, within the spleen. In patients with hypersplenism, up to 90% of the platelets can be found in the spleen.

After labeled platelets are injected, there is accumulation in both the liver and the spleen. An initial, irreversible phase of hepatic uptake occurs. This equilibrates during the first 5 minutes and may reflect hepatic clearance of platelets damaged during the labeling procedure. Simultaneously, there is a slow increase in activity over the spleen that peaks in about 20 minutes. Splenic platelet uptake depends on input (spleen blood flow) and output (clearance).

The splenic platelet pool size can decrease and the platelet count increase with intravenous infusions of epinephrine in normal persons and in patients with splenomegaly. By contrast, isoprenaline increases the splenic pool size. Splenic blood flow increases with increasing spleen size, although perfusion (flow per unit of tissue volume) falls. Blood flow can increase in some inflammatory disorders (e.g., SLE) without an increase in spleen size. A marked increase or decrease in splenic perfusion alters the proportion of platelets within the spleen.

Fig. 130.3 shows why approximately 30% of the platelets are normally present in the spleen.[2] Because about 5% of cardiac output goes to the spleen and because the average splenic transit time (i.e., the time for the platelet to pass through the spleen) is approximately 10 minutes—compared with the usual average time of 1 minute for a platelet to make a complete circulatory pass—approximately one-third of the platelets are within the spleen (i.e., 5%×10 minutes/95%×1 minute, or a ratio of 50 : 95, or ≈1:2). With hypersplenism, the splenic blood flow can increase up to fivefold (i.e., from 5% to 25% of total blood flow). Thus, even without an increase in splenic transit time, 70% or more of the platelets can be reversibly sequestered within the spleen.

The most important determinant of the splenic platelet pool is the spleen size. The measurement of spleen size can thus be helpful in predicting the degree of thrombocytopenia expected from excess platelet pooling in the spleen. For example, if 90% of the platelet pool is in the spleen (i.e., 10% outside the spleen), the platelet count

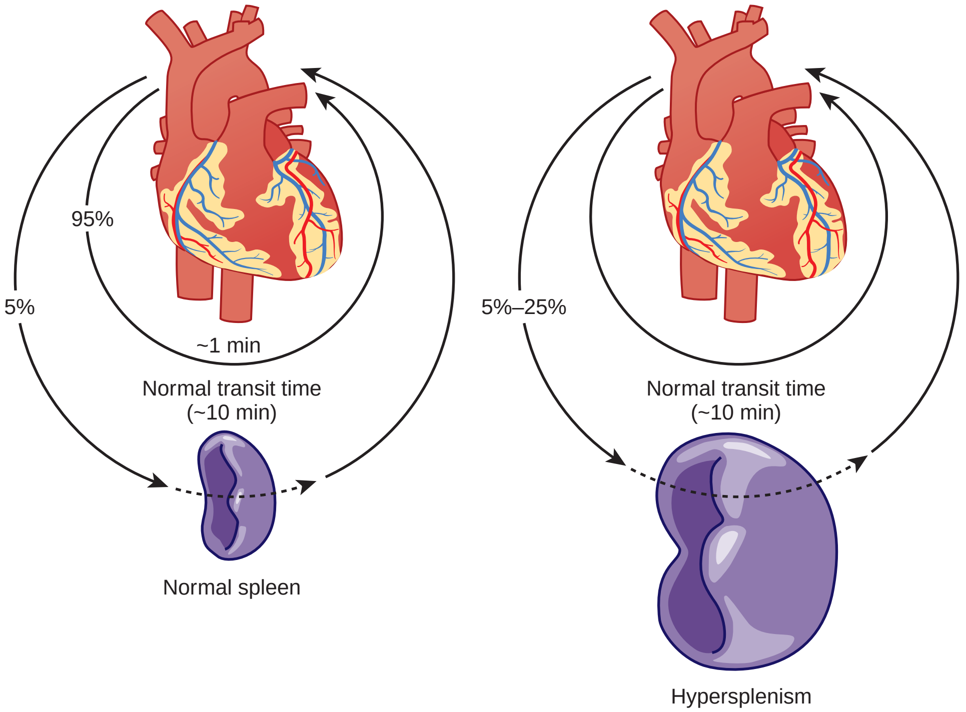

Figure 130.3 PHYSIOLOGIC AND PATHOLOGIC PLATELET SPLENIC SEQUESTRATION. Normally, about 5% of cardiac output is to the spleen; however, a platelet that enters the spleen spends about 10 minutes there (splenic transit time = 10 minutes). In contrast, it usually takes only about 1 minute for a platelet to make a circulatory pass elsewhere. Thus, at any one time about one-third of the platelets are located within the spleen: (5% × 10 minutes):(95% × 1 minute), or an approximate 1:2 ratio. In hypersplenism, the splenic blood flow can increase by a factor of 5, that is, from 5% to 25% of total blood flow per minute. Thus, even without increase in splenic transit time, up to 70% or more of the platelets can be reversibly sequestered within the spleen. *(From Arnold DM, Warkentin TE. Thrombocytopenia and thrombocytosis. In: Wilson WC, Grande CM, Hoyt DB, eds. Trauma: critical care. Vol. 2. New York: Informa Healthcare USA; 2007:983.)*

will be reduced by sevenfold because normally, 70% of platelets lie outside the spleen. Consequently and as a general rule, even if the spleen is massively enlarged, severe thrombocytopenia ($<20 \times 10^9$/L) is unusual. On the other hand, mild thrombocytopenia may be explained by mild splenomegaly that may not be detectible on physical examination but can be seen with imaging studies.

PATHOLOGIC PLATELET SEQUESTRATION: HYPERSPLENISM

Definition

Hypersplenism is a syndrome characterized by splenomegaly and any or all of the following cytopenias: anemia, leukopenia, or thrombocytopenia. Implicit in the definition is that the cytopenias will correct after splenectomy. Although splenomegaly is almost always present in hypersplenism, some patients with splenomegaly do not have hypersplenism. Hypersplenism usually is the result of an identifiable pathologic process, but rarely, the cause of the splenomegaly remains elusive, and the hypersplenism is termed *primary*.

Pathogenesis

A list of disorders producing splenomegaly and hypersplenism is presented in Table 130.2. An increase in the size of the spleen can be caused by several mechanisms. Increased workload of the spleen can be caused by immunologic stress (infection, inflammation, or an autoimmune disorder) or by increased RBC removal (RBC membrane disorders, hemoglobinopathies). Portal hypertension also increases the size of the spleen, producing congestive splenomegaly. Benign and malignant infiltrative disorders may increase splenic size (infiltrative splenomegaly) and cause hypersplenism. Some of these disorders produce thrombocytopenia by more than just hypersplenism (e.g., BM infiltration with tumor, immune-mediated platelet clearance). Thus the demonstration of an enlarged spleen does not necessarily mean that the cytopenias are solely the result of hypersplenism.

Thrombocytopenia of hypersplenism is caused primarily by increased splenic platelet pooling. A massively enlarged spleen can hold more than 90% of the total platelet mass. Without altered platelet production, the total body platelet mass usually is normal, and the platelet life span is near normal. Usually, the splenic transit time remains normal (≈10 minutes), but the absolute number of platelets retained within the enlarged spleen is increased. All the sequestered platelets remain part of the exchangeable pool. In hypersplenism, the thrombocytopenia is moderately severe (platelet counts of 50×10^9/L to 150×10^9/L). Severe thrombocytopenia ($<20 \times 10^9$/L) suggests another diagnosis, or (in the setting of advanced liver disease) concomitant contributors such as hyperfibrinolysis and decreased (hepatically synthesized) thrombopoietin production. It is unusual for patients with hypersplenism alone to have evidence of hemostatic impairment attributable to thrombocytopenia or to need specific interventions to raise the platelet count. Plasma volume expansion occurs in hypersplenism, but hemodilution plays a relatively minor role in the thrombocytopenia.

The neutropenia of hypersplenism is caused by an increase in the marginated granulocyte pool, a portion of which is located in the spleen. The neutropenia of hypersplenism is usually asymptomatic.

Diagnosis

Thrombocytopenia is likely to be caused by hypersplenism when (1) splenomegaly is present, (2) the thrombocytopenia is mild to

moderate in severity, (3) moderately reduced neutrophil counts and low-normal hemoglobin levels are found, and (4) there is no or minimal evidence of impaired hematopoiesis on BM examination. Ultrasonography, computed tomography, and radionuclide imaging are of comparable sensitivity for documenting splenomegaly, and an imaging study should be performed if splenomegaly is not evident on physical examination. The mean platelet volume is often slightly decreased in hypersplenism, but this finding is not sufficiently specific to be diagnostically useful. An ^{111}In-labeled platelet survival study can be diagnostic of hypersplenism, demonstrating reduced platelet recovery and a normal platelet life span. Determining the cause of the splenomegaly is usually the most important issue.

Therapy

Several maneuvers can improve or correct the cytopenias attributable to hypersplenism, including total or partial splenectomy; partial splenic embolization; and in patients with congestive splenomegaly, surgical or transjugular intrahepatic portosystemic shunting. However, cytopenias secondary to hypersplenism and thrombocytopenia are almost never of sufficient severity to justify such treatment. Consequently, the decision to perform one of these interventions usually depends on other considerations. For example, splenectomy should be considered for pain relief or early satiety associated with massive splenomegaly (e.g., in myelo- or lymphoproliferative disorders) or for splenomegaly of unknown origin (for investigation of possible splenic lymphoma).

Short-term complications from splenectomy include infections, bleeding, and thromboembolism. The major long-term risk associated with splenectomy is overwhelming septicemia; this risk can be reduced by vaccination. All patients should be vaccinated against pneumococci, meningococci, and *Haemophilus* species at least 2 weeks before elective splenectomy. Moreover, "booster" doses of pneumococcus and meningococcus vaccines are recommended after 5 years.[14] Splenectomy for congestive hypersplenism in the setting of portal hypertension is associated with high morbidity and mortality rates. Splenectomy is also associated with high morbidity (50%) and mortality (10% to 15%) rates in myeloid metaplasia and does not alter the natural history of this disorder. Thus, splenectomy is usually performed for palliation of intractable symptoms.

Splenectomy in Gaucher disease usually corrects the cytopenias, relieves abdominal discomfort, and improves growth in children. Partial, rather than total, splenectomy has been used to avoid shifting the deposition of glucocerebroside from the spleen to the bones. Often, however, splenomegaly and hypersplenism recur after partial splenectomy. Enzyme replacement therapy can reduce the morbidity from hypersplenism (see Chapter 54).

DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Many drugs can cause thrombocytopenia. Some drugs (e.g., anticancer chemotherapeutic agents, linezolid,[15] valproic acid[16]) cause dose-dependent thrombocytopenia, generally through myelosuppressive mechanisms. An important disorder encountered by hematologists is unexpected thrombocytopenia caused by immunologic (idiosyncratic) mechanisms.[17–20] The frequency of these reactions varies considerably among drugs, but is generally very rare (<1:10,000) for commonly used drugs such as acetaminophen, indomethacin, naproxen, quinine, and trimethoprim-sulfamethoxazole (TMP-SMX). The most frequently implicated drugs are vancomycin, TMP-SMX, piperacillin, rifampin, and oxaliplatin.

Immunologic drug-induced thrombocytopenia can occur through different mechanisms (Fig. 130.4). For example, thrombocytopenia can occur when the Fab terminus of the pathogenic IgG binds to a complex composed of drug (or drug metabolite) and a platelet membrane component (typically, platelet GPIIb/IIIa or GPIb/IX/V). The Fc portions of the pathogenic IgG molecules do

Figure 130.4 MECHANISMS OF DRUG-INDUCED IMMUNE THROMBOCYTOPENIA. Four immune thrombocytopenic syndromes are illustrated. On the bottom of the schematic platelet, heparin-induced thrombocytopenia (HIT) is illustrated, indicating that immunoglobulin G (IgG) antibodies bind to complexes of platelet factor 4 (PF4) and heparin, with the Fc regions of the antibodies binding to the platelet FcγIIa receptors, resulting in platelet activation (including generation of procoagulant, platelet-derived microparticles). On the *top* of the schematic platelet, three mechanisms are illustrated that lead to increased platelet clearance by phagocytic cells. From left to right, these are (1) autoantibody-induced immune thrombocytopenia (e.g., gold-induced anti-glycoprotein V [GPV] antibodies). (2) Drug-dependent antibodies reactive against drug (or drug metabolite)–platelet glycoprotein complex(es) (e.g., quinine-induced thrombocytopenia in which drug-dependent antibodies against GPIbα, GPIX, GPIIb, and GPIIIa have been implicated, resulting in an antibody/drug/glycoprotein ternary complex), and (3) antibodies against neoepitope(s) formed in the presence of a drug (e.g., eptifibatide-induced immune thrombocytopenia caused by formation of a ligand-induced binding site elsewhere on the GPIIb/IIIa complex after eptifibatide binding). Note that preexisting (naturally occurring) antibodies can explain abrupt-onset thrombocytopenia in a patient receiving eptifibatide for the first time.

not bind to platelets but interact with Fc receptors on phagocytic cells of the reticuloendothelial system, which ingest the platelets, leading to accelerated platelet clearance. Severe thrombocytopenia (platelet counts $<20 \times 10^9$/L) is typically observed. This mechanism is exemplified by quinine- and vancomycin-induced thrombocytopenia. A complicating issue is that quinine and quinidine can also rarely cause thrombocytopenia with a clinical picture of microangiopathic hemolysis and/or DIC.

Sometimes, the Fab terminus binds to a neoepitope on platelet GPIIb/IIIa induced by the drug, and the drug itself is not part of the neoepitope. This mechanism is exemplified by the GPIIb/IIIa receptor antagonists, eptifibatide and tirofiban, which bind to the Arg-Gly-Asp recognition site on GPIIb/IIIa, forming a neoepitope to which the "fiban-dependent" antibodies bind. In contrast, the GPIIb/IIIa receptor antagonist, abciximab (a human/murine chimeric Fab fragment specific for GPIIIa) can lead to severe immune thrombocytopenia if the patient has antibodies (preexisting or acquired) that recognize the murine component of the chimeric antibody.

Another distinct form of drug-induced thrombocytopenia is exemplified by HIT (see Chapter 130). In this disorder, the Fab portion of the pathogenic IgG binds to platelet factor 4 (PF4), an α-granule protein that is immunogenic when complexed to heparin or certain other polyanions. The Fc portions of the IgG molecules bind to platelet FcγIIa receptors, initiating intense platelet activation (see Fig. 130.4). Perhaps because HIT is a platelet activation syndrome or because of the relatively low number of HIT antibodies that bind to platelet surfaces, the thrombocytopenia is typically mild to moderate rather than severe (see Fig. 131.3 in Chapter 131).

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA

A large number of drugs can cause a syndrome that mimics acute ITP (D-ITP); however, there are relatively few drugs—approximately two dozen—for which causation is well established on both clinical and serologic grounds (Table 130.3).[21–24] Typically, severe thrombocytopenia (platelet count usually $<20 \times 10^9$/L), together with petechiae and purpura, develop within approximately 1 week (although occasionally much longer) after initiation of therapy with the responsible drug. D-ITP is much less common than HIT. For example, a relatively "common" cause of this syndrome is TMP-SMX (co-trimoxazole),

Heparin, as a trigger of heparin-induced thrombocytopenia (HIT), a distinct disorder, is not included in this table.

D-ITP, Drug-induced immune thrombocytopenia; *IFN*, interferon; *TNF*, tumor necrosis factor.

[a] More than 10 patients identified in Milwaukee lab.

[b] Subtype of D-ITP where patient's antibodies (either naturally occurring or that are formed after treatment with abciximab) bind to platelet GPIIb/IIIa after binding of abciximab (chimeric human-murine Fab that recognizes GPIIb/IIIa) to platelets.

[c] Subtype of D-ITP caused by fiban-dependent antibodies (either naturally occurring or formed after treatment with eptifibatide or tirofiban) that recognize neoepitopes on platelet GPIIb/IIIa that form after binding of fiban drug to GPIIb/IIIa.

[d] Gold induces autoantibodies, not typical drug-dependent antibodies.

even though it occurs in only approximately 1 in 25,000 patients who receive this drug combination.

Important exceptions to these generalizations occur with D-ITP that results from GPIIb/IIIa receptor antagonists. These reactions are relatively common (affecting about 0.5% to 1% of patients) and usually occur within hours of first use because of preexisting, naturally occurring antibodies. Another exception is carbimazole-induced thrombocytopenia, in which mild thrombocytopenia is explained by the presence of relatively small quantities of the platelet GP target (platelet endothelial cell adhesion molecule-1 [PECAM-1]) on the platelet surface.[25] Besides the atypical immune-mediated syndromes of HIT and GPIIb/IIIa antagonist thrombocytopenia, the most common drugs (in absolute terms) implicated in the causation of classic D-ITP syndrome are quinine (outpatients) and vancomycin (inpatients).[26]

Pathogenesis

Drug-dependent binding of the Fab component of IgG to platelet GP leads to platelet destruction. This occurs because the IgG-sensitized platelets are recognized by Fc receptors of phagocytic cells. For quinine- and quinidine-induced ITP, both the GPIIb/IIIa and GPIb/IX/V complexes have been implicated as targets for the drug-dependent IgG (see Fig. 130.4). By contrast, for sulfa antibiotic- and naproxen-induced ITP, the GPIIb/IIIa complex is predominantly involved. Sometimes, drug metabolites form the antigen rather than the parent drug. A trimolecular complex is formed among IgG Fab, the drug (or metabolite), and the platelet GP. In contrast to HIT, platelet Fc receptors are not involved in D-ITP pathogenesis. Drug-dependent IgG binding is remarkably heterogeneous with respect to binding affinity, number of binding sites per platelet, and the range of drug concentrations required. A study of quinine-induced ITP identified two different types of antibodies: quinine-dependent antibodies that bound to platelets in the presence of drug and quinine-specific antibodies that reacted with quinine-conjugated albumin.[27] The pathophysiologic implications of this latter group of antibodies remain unclear.

The fundamental mechanism that accounts for antibody formation in a small proportion of patients is unknown. One group has proposed that drug-dependent platelet-reactive antibodies are derived from a pool of naturally occurring autoantibodies with inherently weak (nonpathological) affinity for certain platelet membrane GPs.[17,27] However, if a certain drug is able to enhance antibody–antigen interaction, and if B cells expressing such antibodies are induced to proliferate and undergo affinity maturation in such a patient, the resulting antibody can destroy the platelets in the presence of the drug.

Clinical Features

Patients with D-ITP typically present with petechiae, purpura, and severe thrombocytopenia (platelet count often $<20 \times 10^9$/L). Systemic symptoms, such as fever and chills, may occur in patients with abrupt-onset thrombocytopenia. Usually, the thrombocytopenia becomes clinically apparent 1 to 2 weeks after initiation of the drug, but the thrombocytopenia can start after a patient has been taking a drug for several years. Typically, the platelet count begins to rise a few days after stopping the implicated drug, but occasionally several weeks are required for recovery, possibly because of the generation of drug-independent IgG (platelet autoantibodies).

Sometimes, drug exposure is relatively obscure. Among outpatients, the physician needs to inquire about potential exposure to quinine. Quinine is widely available—for example, as an ingredient in tonic water, as an additive to street drugs, and in some countries as therapy for leg cramps. Vancomycin is a relatively common cause of D-ITP in hospitalized inpatients. Most often, this occurs after the usual intravenous administration, but some reports have implicated exposure via orthopedic cement or with peritoneal administration of vancomycin.

Rarely, distinct drug-dependent IgG molecules destroy RBCs or WBCs in addition to platelets. For example, both platelet- and leukocyte-reactive quinidine-dependent IgG molecules have been detected in a patient with quinidine-induced bicytopenia. Sometimes, the immune process is directed against a pluripotent hematopoietic stem cell, resulting in pancytopenia accompanied by BM aplasia or hypoplasia (e.g., gold-, carbamazepine-, or quinidine-induced pancytopenia). A BM aspirate should be performed in patients with suspected drug-induced bicytopenia or pancytopenia because a hypoplastic BM may be indicative of drug-induced aplastic anemia.

Diagnosis

A high index of clinical suspicion is required to make the diagnosis. Moreover, clinicians need to evaluate which drug (often among several that the patient is receiving) is most likely to explain a diagnosis of D-ITP.[21–24] The clinician should focus on drugs that have been started 5 to 10 days before the onset of the platelet count decrease (Fig. 130.5A). Also, with drugs such as quinine, in which there may be intermittent exposure (e.g., consumption of gin and tonic), a very recent exposure (previous 1 or 2 days) usually explains the abrupt onset of symptomatic thrombocytopenia.

After the physician has identified one or more potential agents, the next step is to determine whether these drugs have previously been implicated as causes of D-ITP. The box Search Strategies When Investigating a Patient With Possible Drug-Induced Immune Thrombocytopenic Purpura includes some strategies for identifying drugs implicated in D-ITP[28–31].

SEARCH STRATEGIES WHEN INVESTIGATING A PATIENT WITH POSSIBLE DRUG-INDUCED IMMUNE THROMBOCYTOPENIC PURPURA

Three sources of information as to whether a drug has been implicated as a cause of D-ITP:

- **PubMed search** (http://www.pubmed.ncbi.nlm.nih.gov): (name of drug) and (thrombocytopenia). By way of example, the author encountered a patient who developed severe thrombocytopenia 5 days after starting treatment with mirtazapine. Searching (mirtazapine) and (thrombocytopenia) in December 2014 identified two reports[28,29] of mirtazapine-induced D-ITP syndrome. By 2020, mirtazapine-induced D-ITP was an established entity.[30]
- **Drug-induced thrombocytopenia website** (http://www.ouhsc.edu/platelets/ditp.html): Investigators at the University of Oklahoma published a comprehensive survey of drugs implicated in D-ITP using clinical criteria[21]; a website maintained by these investigators is updated every 2 years (last updated, 2018[22]).
- **Database from drug-dependent platelet-reactive antibody testing** at the BloodCenter of Wisconsin, 1995–present (http://www.ouhsc.edu/platelets/InternetPostingLab2_18_11Frames.htm): the BloodCenter of Wisconsin maintains a website reporting its experience in detecting drug-dependent platelet-reactive antibodies.[31]

Demonstration of drug-dependent binding of IgG to platelets in vitro can be important for diagnosis (see Fig. 130.5B). Labeled Ig-specific probes (e.g., flow cytometry assays) or GP capture techniques (e.g., MAIPA) can be used. In other cases, D-ITP test results are negative, but the diagnosis still seems likely based on clinical features and supporting literature.

There are certain caveats in diagnostic testing. First, metabolites must sometimes be used instead of the parent drug to detect the IgG.

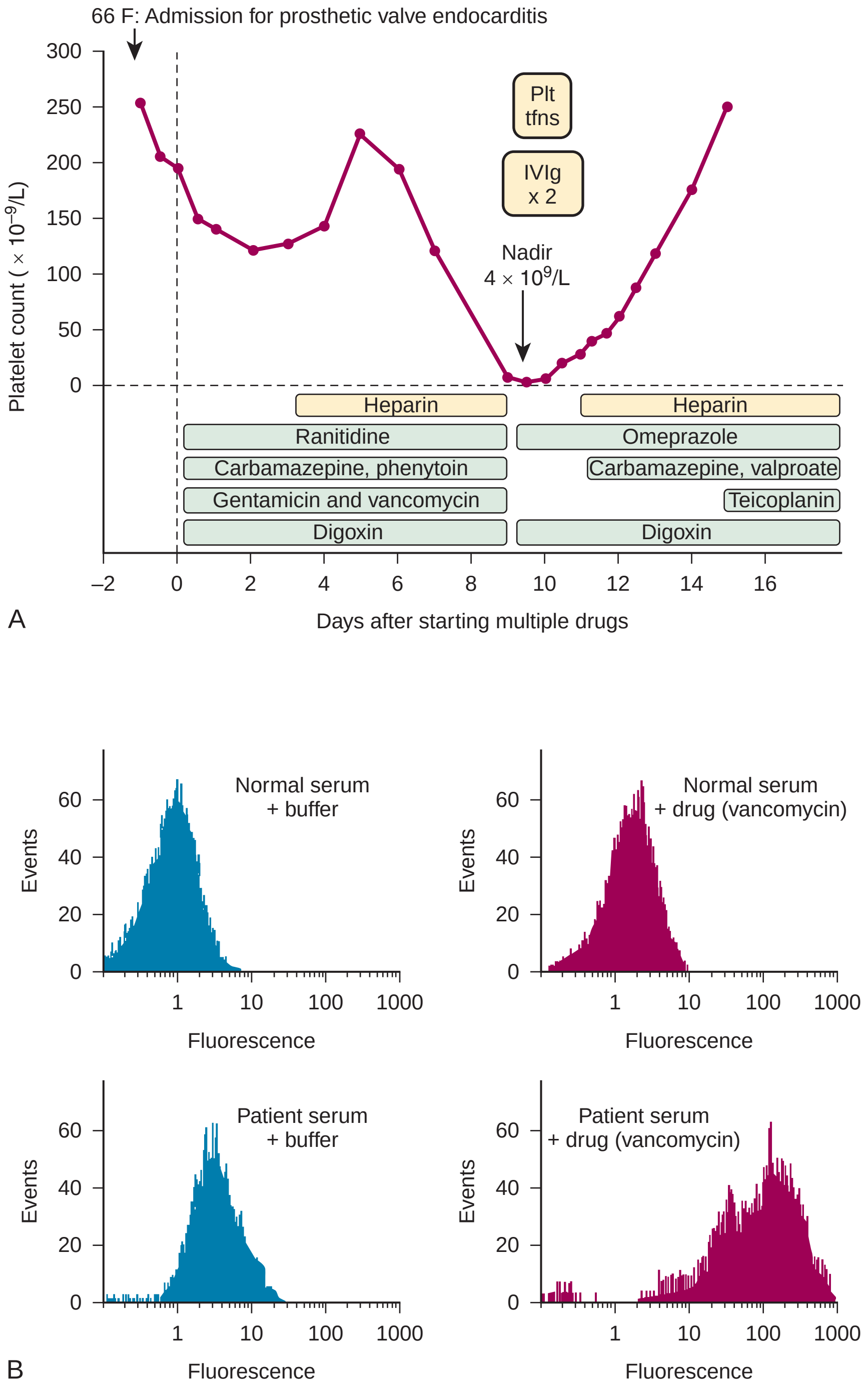

Figure 130.5 DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (D-ITP) SECONDARY TO VANCOMYCIN. (A) Timeline of drug-induced immune thrombocytopenia (D-ITP). A 66-year-old woman was admitted for prosthetic valve endocarditis 5 months after undergoing mitral valve replacement. The initiation of multiple new drugs and the onset 6 days later of progressively severe thrombocytopenia (platelet count nadir, 4×10^9/L on day 9) suggested D-ITP syndrome. However, the timing fit several drugs (ranitidine, carbamazepine, phenytoin, gentamicin, vancomycin, and digoxin). (B) Drug-dependent binding of antibodies was demonstrated using patient serum and vancomycin. Also, test results for heparin-induced thrombocytopenia antibodies were negative. Thus the diagnosis of vancomycin-induced D-ITP syndrome was made based on clinical and serological grounds. The patient received treatment with high-dose intravenous immunoglobulin (IVIG) and platelet transfusions. *Plt tfns*, Platelet transfusions.

Second, the target drug (or metabolite) must be included in the wash buffer used in these assays. Third, despite these maneuvers, the sensitivity of in vitro assays is relatively low, and the diagnosis of D-ITP must often be made on clinical grounds. Sometimes, the diagnosis is confirmed by inadvertent or deliberate reexposure to the suspected drug. However, deliberate drug challenge is not often performed because of its potential risk.

An intriguing approach to identify drug-dependent platelet-reactive antibodies was reported by investigators at the Milwaukee Blood Center.[32] They used nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice (which lack xenoantibodies, thereby allowing infused human platelets to circulate) to identify drug-dependent antibodies in patient sera, including antibodies that only recognize drug metabolites (presumably, mice produce the same or similar drug metabolites as humans, which are recognized by the drug-dependent antibodies).

Management

As many drugs as possible should be discontinued in patients with suspected D-ITP. If further drug treatment is necessary, an alternate, immunologically non-cross-reactive substitute should be used. Spontaneous improvement in the platelet count usually begins within a few days of discontinuing the offending drug, although in some cases, complete recovery may take 2 weeks or longer. Platelet transfusions should be given to patients with life-threatening bleeding. High-dose intravenous immunoglobulin (IVIg), 1 g/kg given over 6 to 8 hours, with a second dose 1 or 2 days later if required, may be helpful in some situations. Corticosteroids appear to be relatively ineffective for treatment of D-ITP.

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA OF RAPID ONSET

A rapid onset of thrombocytopenia (within hours) can occur if a patient with preexisting drug-dependent antibodies is (re)exposed to the drug.[33] This situation is relatively common in HIT (≈25% of patients identified)[5] because repeated treatment with heparin is common and heparin use itself can result in the complication (HIT-associated thrombosis) that might lead to further use of heparin. Because HIT antibodies are transient, however, rapid-onset HIT occurs in patients with recent heparin exposures, usually within the past 100 days.[5] By contrast, repeated episodes of quinine-induced thrombocytopenia of abrupt onset can occur many months or even years apart because these antibodies persist for much longer. Thrombocytopenia of rapid onset is commonly seen with GPIIb/IIIa receptor antagonists (see next section).

THROMBOCYTOPENIA CAUSED BY GLYCOPROTEIN IIB/IIIA RECEPTOR ANTAGONISTS

Several thrombocytopenic syndromes have been reported with use of GPIIb/IIIa receptor antagonists (abciximab, eptifibatide, tirofiban) administered during percutaneous coronary intervention (e.g., angioplasty, stenting): (1) rapid-onset, severe thrombocytopenia within 12 hours of drug administration (in 0.4% to 2% of patients), (2) rapid-onset pseudothrombocytopenia (in approximately 1% of patients exposed to abciximab [ReoPro]), (3) rapid-onset thrombocytopenia within 12 hours of a second exposure to a GPIIb/IIIa antagonist, and (4) delayed-onset thrombocytopenia beginning 4 to 7 days after drug administration (rare).[6] The frequency of rapid-onset thrombocytopenia is higher among patients who receive a second course of therapy, especially if it follows the initial exposure by only a few weeks. Thrombocytopenia is typically severe (median platelet count nadir, about 5 × 10^9/L to 10 × 10^9/L), but clinical effects vary dramatically, ranging from absence of petechiae or other signs of bleeding (in 50% of patients) to fatal hemorrhage (in less than 5%). Some patients develop anaphylactoid reactions accompanying the abrupt platelet count declines. The antibodies may cause thrombosis in some patients, likely because the pathogenic antibodies also activate platelets.[6] Fig. 130.6 illustrates an example of delayed-onset, abciximab-induced thrombocytopenia; in such patients, high-titer antibodies triggered by abciximab recognize

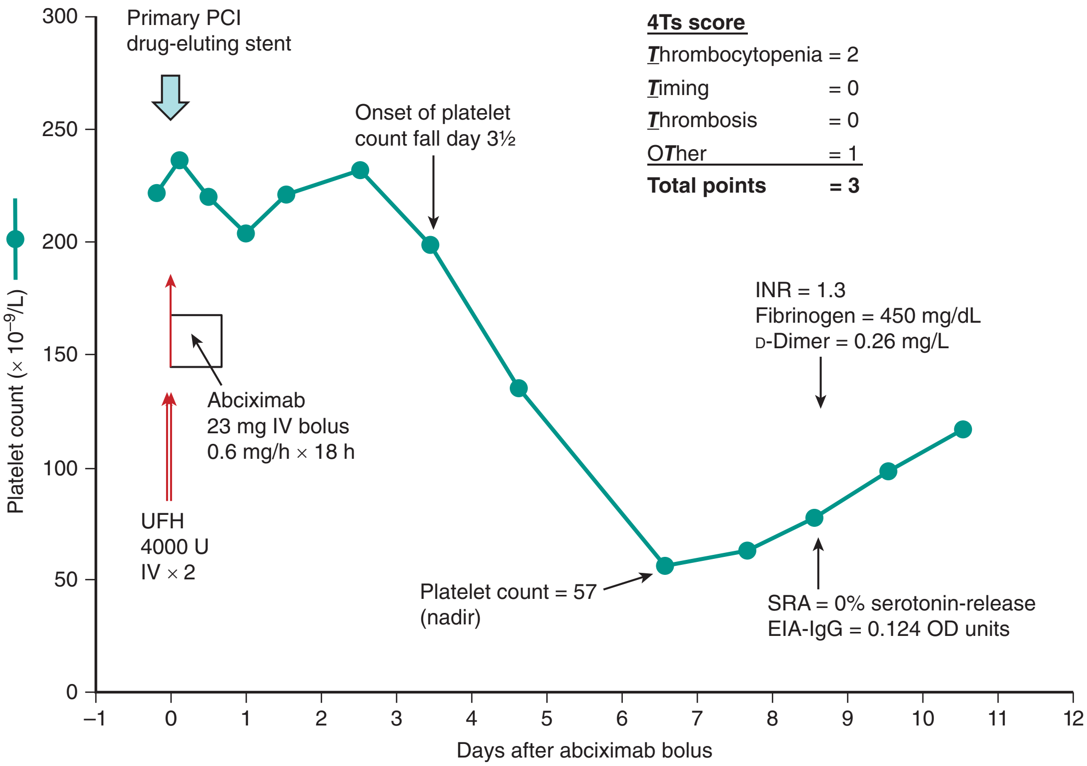

Figure 130.6 DELAYED-ONSET ABCIXIMAB-INDUCED IMMUNE THROMBOCYTOPENIA. Moderate thrombocytopenia (platelet count nadir, 57 × 10^9/L) in an elderly patient started several days after percutaneous coronary intervention (PCI) during which unfractionated heparin (UFH) and abciximab were administered. This sequence of events suggested immune thrombocytopenia triggered either by heparin (delayed-onset heparin-induced thrombocytopenia [HIT]) or abciximab. The unusually early onset of thrombocytopenia (day 3½), the normal D-dimer (reference range <0.50 mg/L), and negative HIT antibody assays ruled out HIT. *EIA*, Enzyme-immunoassay; *INR*, international normalized ratio; *IV*, intravenous, *OD*, optical density; *PCI*, percutaneous coronary intervention; *SRA*, serotonin-release assay; *U*, units.

platelets to which abciximab remains irreversibly bound several days post-exposure.

These syndromes are caused by at least three mechanisms. First, antibodies of IgG (and possibly IgM) class can bind to neoepitopes on the GPIIb/IIIa complex generated by these drugs (or their metabolites); that is, ligand-induced binding sites (see Fig. 130.4). Up to 5% of humans and nonhuman primates have naturally occurring IgG antibodies that will bind to GPIIb/IIIa receptors in the presence of drug, which could explain why rapid-onset thrombocytopenia occurs so frequently with these agents. A second mechanism is applicable to abciximab, a chimeric Fab fragment comprised of murine GPIIb/IIIa-reactive sequences and human framework sequences. Interestingly, although a high frequency of normal persons (74%) have antibodies that recognize platelets coated with abciximab, these "normal" antibodies were shown to differ from those detected in patients in whom thrombocytopenia developed after a second exposure to abciximab: whereas the pathogenic antibodies recognized murine sequences within abciximab, the "normal" (nonpathogenic) antibodies were specific for the carboxyl terminus (papain cleavage site) of Fab fragments prepared from normal human IgG. Drug-dependent antibodies can also be generated about 1 week after exposure. The antibodies differ among patients with respect to the precise neoepitopes recognized and display variable degrees of cross-reactivity among the different GPIIb/IIIa receptor antagonists ("fibans"). This explains why a repeat treatment course with another GPIIb/IIIa receptor antagonist may not necessarily cause thrombocytopenia. A third mechanism involves eptifibatide-dependent antibodies that activate platelets via their FcγIIa receptors.[6]

Some naturally occurring antibodies only bind to GPIIb/IIIa when the calcium concentration is low, thus explaining pseudothrombocytopenia—falsely low platelet count estimates caused by ex vivo aggregation of platelets in blood samples collected into calcium-chelating anticoagulants, especially EDTA.

Platelet transfusions are indicated in patients who are bleeding, although their efficacy has not been established. Platelet transfusions are most likely to be effective for treating abciximab-induced thrombocytopenia because the drug binds so tightly to GPIIb/IIIa that little abciximab is free to bind to the transfused platelets. Platelet transfusions are not indicated in pseudothrombocytopenia, which underscores the importance of reviewing the blood film when a low platelet count is reported after treatment with one of these agents.

Various in vitro assays using flow cytometry or enzyme-linked immunosorbent assay (ELISA) have been developed to detect these antibodies. Because some pathogenic antibodies are naturally occurring, it is theoretically possible to identify patients at high risk for rapid-onset thrombocytopenia in elective situations (see box on Approach to Patients With Thrombocytopenia Following Percutaneous Coronary Intervention).

APPROACH TO PATIENTS WITH THROMBOCYTOPENIA FOLLOWING PERCUTANEOUS CORONARY INTERVENTION

Acute-onset thrombocytopenia

Four diagnoses should be considered in patients who develop thrombocytopenia within minutes or a few hours after a PCI and have received one or more of the following agents: (1) platelet GPIIb/IIIa inhibitor (e.g., abciximab, eptifibatide, tirofiban), (2) heparin, or (3) iodinated contrast agent.

- **GPIIb/IIIa inhibitor–induced pseudothrombocytopenia**. The patient has no symptoms or signs of bleeding, and platelet aggregates are seen in the blood film. The platelet count is falsely reported as low by the automated particle counter, which fails to count aggregated platelets. No treatment is required.
- **GPIIb/IIIa inhibitor–induced thrombocytopenia**. The platelet count falls abruptly, often to profoundly reduced levels (typical nadir, $<20 \times 10^9$/L). Hemostatic impairment is variable, ranging from petechiae to fatal hemorrhages; occasionally, patients develop anaphylactoid reactions or even associated thrombosis. Treatment involves stopping all platelet antagonists and anticoagulants and giving platelets if the patient has signs of bleeding. Prophylactic platelet transfusions can also be considered if the platelet count is very low (e.g., $<10 \times 10^9$/L). Testing for drug-dependent antibodies can be accomplished using flow cytometry or ELISA.
- **Rapid-onset HIT**. In patients who have preexisting HIT antibodies because of recent heparin exposure (generally within the past 100 days), rapid-onset HIT can occur when heparin is given during PCI. This is much less common than GPIIb/IIIa inhibitor–induced thrombocytopenia or pseudothrombocytopenia, so presumptive treatment of HIT with a nonheparin anticoagulant is rarely indicated in this situation. The platelet count nadir is usually much higher than with GPIIb/IIIa inhibitor–induced thrombocytopenia.
- **Radiocontrast-induced ITP**. Very rarely, patients who have previously received iodinated contrast can develop abrupt-onset, severe thrombocytopenia after exposure to contrast during PCI. Platelet transfusions (with or without high-dose IVIg) are appropriate for a bleeding patient.

Delayed-onset thrombocytopenia

Fig. 130.6 illustrates the clinical and laboratory course of a patient who developed thrombocytopenia approximately 1 week after PCI. The differential diagnosis consisted of delayed-onset HIT versus delayed-onset abciximab-induced thrombocytopenia. Ultimately, the diagnosis of HIT was discarded because (a) the onset of thrombocytopenia (day 3½) was too soon for HIT; (b) normal D-dimer argued against HIT-associated hypercoagulability, and (c) testing for HIT antibodies was negative. Thus, the patient most likely had delayed-onset, abciximab-induced thrombocytopenia.

ELISA, Enzyme-linked immunosorbent assay; *HIT,* heparin-induced thrombocytopenia; *ITP*, induced thrombocytopenia; *IVIg*, intravenous immunoglobulin; *PCI*, percutaneous coronary intervention.

Malignancy

Thrombocytopenia complicating malignant disorders most frequently results from antineoplastic treatment or BM replacement by tumor. However, certain thrombocytopenic syndromes have been associated with malignancy, including autoimmune thrombocytopenia, DIC, and TMA.

ITP attributable to platelet GP-reactive autoantibodies can complicate neoplastic lymphoproliferative diseases such as Hodgkin disease, non-Hodgkin lymphoma, chronic lymphocytic leukemia, and multiple myeloma. Sometimes, the thrombocytopenia responds to treatment of the neoplasm, although in some patients (particularly those with Hodgkin disease), the thrombocytopenia is indistinguishable from ITP and is not related to the activity of the lymphoma.

DIC occurs with certain malignancies, particularly adenocarcinoma of the pancreas, stomach, lung, colon, breast, and prostate (see Chapter 137). Some patients present with venous or, less commonly, arterial thrombosis as the first clinical manifestation of their malignancy. In these patients, the presence of thrombocytopenia is an important clue that should prompt investigations for DIC, such as measurement of fibrinogen and D-dimer levels. In the author's experience, the platelet count typically rises to normal or even elevated levels with heparin therapy because heparin ameliorates the DIC process; however, recurrent thrombocytopenia and thrombosis can occur within hours of discontinuing the heparin therapy (Fig. 130.7).[34] Cancer patients with DIC and venous thrombosis are also at increased risk for warfarin-associated venous limb gangrene.[35,36] The role of various tumor-associated procoagulant substances—such as "cancer procoagulant" (a 68-kDa cysteine proteinase that activates factor X independently of tissue factor/factor VIIa) and cancer-associated tissue factor (which is expressed on tumor cells and circulating microparticles)—suggest pathophysiologic parallels with microthrombosis in HIT because both cancer-associated DIC and acute HIT are risk factors for phlegmasia cerulea dolens and venous limb gangrene during anticoagulation with warfarin. Thus, cancer patients with DIC should receive heparin (especially LMWH) rather than

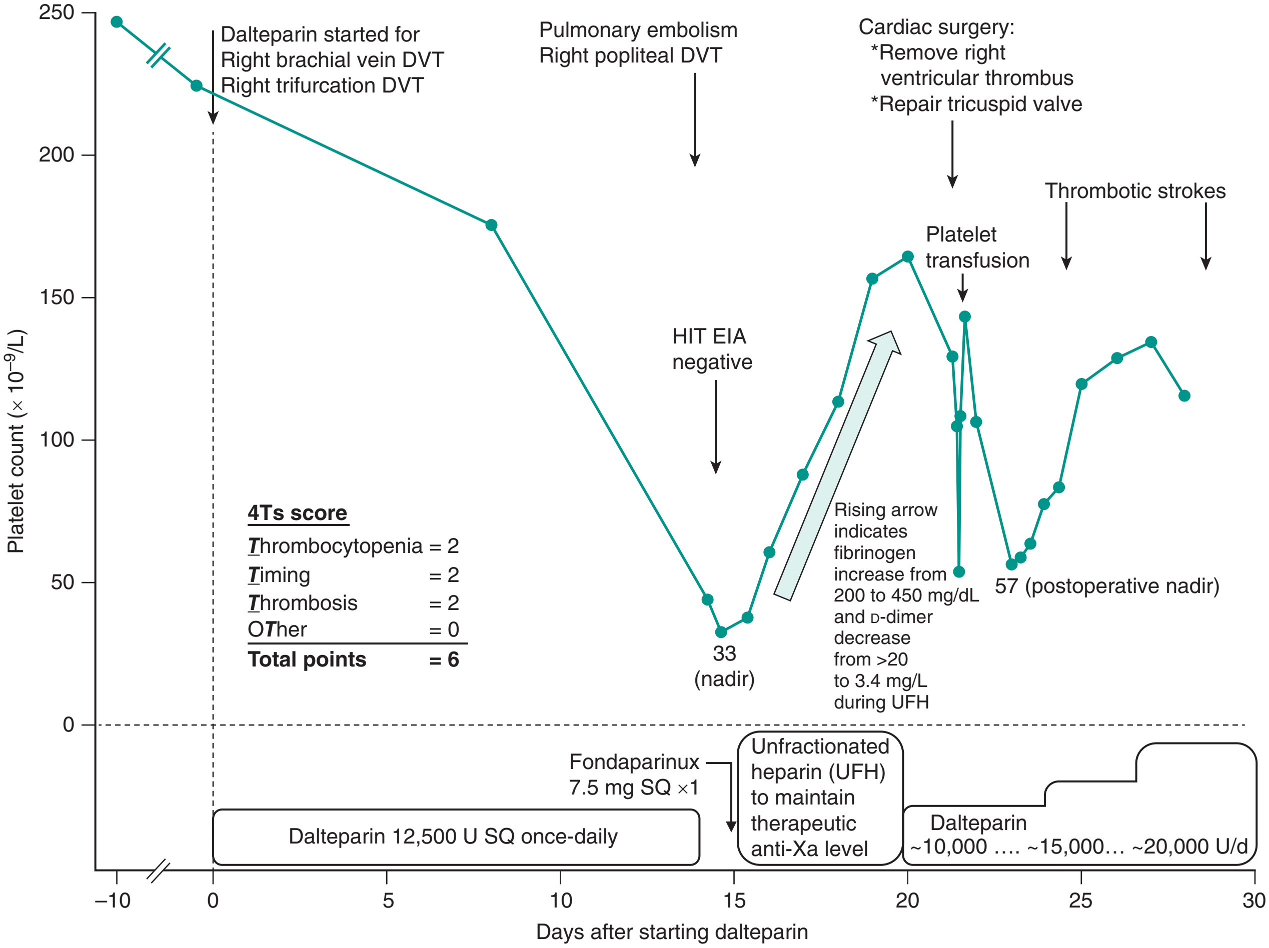

Figure 130.7 CANCER-ASSOCIATED DISSEMINATED INTRAVASCULAR COAGULATION MIMICKING HEPARIN-INDUCED THROMBOCYTOPENIA. This patient was diagnosed with metastatic adenocarcinoma of the lung (malignant pericardial effusion, cerebral, and adrenal metastases), and received dalteparin for brachial and trifurcation deep-vein thrombosis (DVT). Severe thrombocytopenia occurred approximately 2 weeks later. Despite a strong clinical picture for heparin-induced thrombocytopenia (HIT) based on a high 4Ts score (6 points), testing for HIT antibodies was negative by enzyme-linked immunosorbent assay (ELISA). Resumption of heparin resulted in correction of the thrombocytopenia and improvement in markers of disseminated intravascular coagulation (DIC) (rising fibrinogen and falling D-dimer levels). The diagnosis was cancer-associated DIC, with exacerbation of thrombocytopenia when heparin was held or was subtherapeutic. *DVT*, Deep-vein thrombosis; *EIA*, enzyme-immunoassay; *SQ*, subcutaneous; *SRA*, serotonin-release assay; *UFH*, unfractionated heparin.

warfarin anticoagulation (see box on Diagnostic Considerations in the Patient with Limb Ischemia and Thrombocytopenia in Chapter 131). Sometimes, nonbacterial thrombotic endocarditis (“marantic” endocarditis) with associated embolic phenomena (e.g., strokes, splenic infarcts) and DIC can occur in association with metastatic cancer.[37,38]

DIC with hemorrhagic manifestations is characteristically seen in some patients with prostate cancer and in many patients with acute promyelocytic leukemia. It is crucial to recognize promyelocytic leukemia because treatment with all-*trans*-retinoic acid induces differentiation of the malignant cells, thereby rapidly reducing the life-threatening bleeding risks attributable to hyperfibrinolysis. Further, antifibrinolytic therapy (e.g., tranexamic acid), which is generally *contraindicated* in DIC states—can be used to improve hemostasis in hyperfibrinolysis secondary to prostate cancer or promyelocytic leukemia.

A destructive thrombocytopenic disorder that resembles HUS or TTP has been described in patients with advanced cancer. In some patients, mitomycin, gemcitabine, or other drugs may have contributed to the microangiopathy.[39–41] DIC is not usually present. Some patients respond transiently to plasmapheresis, but for many, response to any therapy is poor.

HEMODILUTION AND PLATELET CONSUMPTION AFTER SURGERY

Platelet count declines of 30% to 70% occur universally after major surgery and reflect the combined effects of hemodilution and increased platelet consumption. Such hemodilution-associated thrombocytopenia is especially prominent after cardiac surgery and is proportional to the amount of fluids (crystalloid, colloid, blood products) administered. The platelet count fall is abrupt and is evident immediately after surgery. Dilutional coagulopathy also is responsible for the minor to moderate prolongations in coagulation test results that occur transiently after surgery.

Perioperative hemodilution is usually accompanied by increased platelet consumption related to the effects of surgery. This helps to explain why the postsurgery platelet count usually continues to decline over the next 1 to 3 days, with the postoperative nadir (lowest platelet count value) usually occurring at a median of postoperative day 2, with a range between postoperative days 1 through 4 (Fig. 130.8).[2] Subsequently, there is a rise in the platelet count that peaks at approximately day 14 at levels often two to three times the patient’s preoperative baseline before it returns to baseline over the next 2

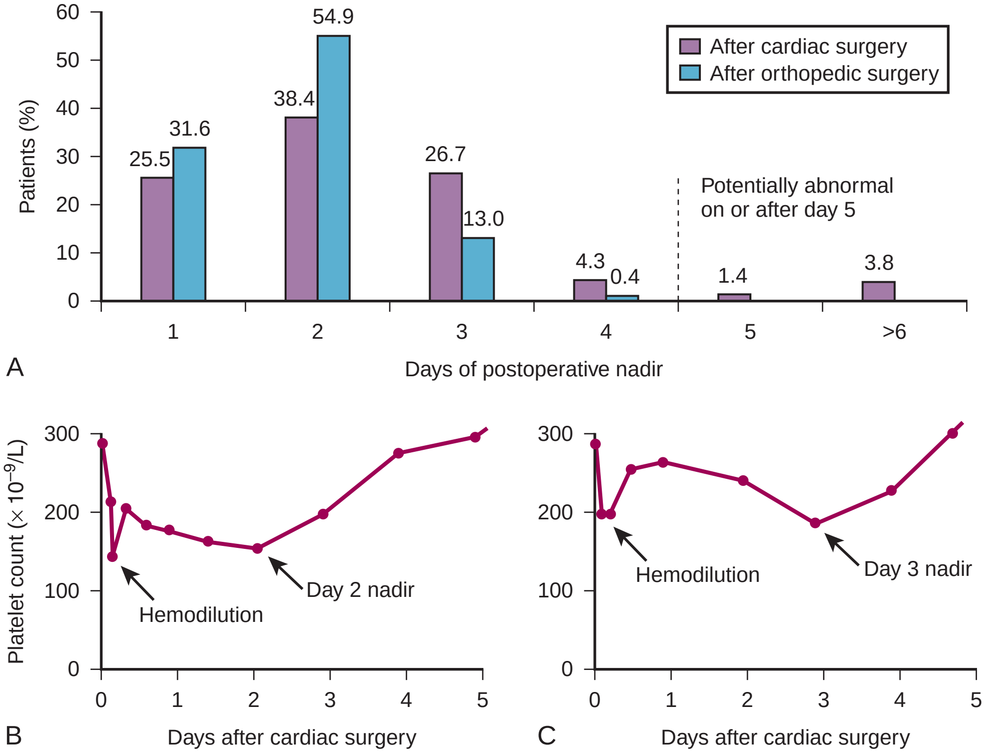

Figure 130.8 EARLY POSTOPERATIVE PLATELET COUNT DECLINES. (A) Distribution of early postoperative count nadirs. For both orthopedic and cardiac surgery patients, day 2 represents the most common day for the postoperative platelet count nadir to occur (data exclude day 0); beyond postoperative day 4, it is likely that a superimposed thrombocytopenic disorder is occurring. (B and C) Representative postcardiac surgery platelet count declines. Both patients illustrate early hemodilution effects (day 0) and subsequent additional early platelet count declines with nadirs on day 2 (B) and day 3 (C). Neither patient received platelet transfusions. *(From Greinacher A, Warkentin TE. Acquired non-immune thrombocytopenia. In: Marder VJ, Aird WC, Bennett JS, et al., eds. weeks (≈day 28). As described earlier in this chapter (see Fig. 130.1), these platelet count changes reflect thrombopoietin physiology.

CHAPTER 131

HEPARIN-INDUCED THROMBOCYTOPENIA

Theodore E. Warkentin

Heparin-induced thrombocytopenia (HIT) is the most important drug-induced immune-mediated cytopenia for several reasons. First, heparin is a widely used anticoagulant (see Chapter 143). Second, HIT is relatively common, occurring in approximately 1% to 3% of postoperative patients, and 0.2% to 0.5% of medical patients, who receive unfractionated heparin (UFH) derived from porcine intestine for 7 to 14 days.[1] Third, HIT frequently causes life- and limb-threatening venous or arterial thrombosis. Fourth, there are several pitfalls of HIT management, including the potential for thrombocytopenia and/or thrombosis to worsen despite stopping heparin, the high risk for warfarin-associated microthrombosis (most often manifesting as venous limb gangrene), and the potential for failure of approved direct thrombin inhibitor (DTI) therapy because of the confounding of activated partial thromboplastin time (aPTT)–monitored dosing that results from HIT-associated coagulopathies. Finally, various off-label therapies are gaining acceptance for treating HIT, including parenteral anticoagulants (fondaparinux, danaparoid), oral agents (rivaroxaban, apixaban), and even high-dose intravenous immunoglobulin (IVIG) to interrupt HIT antibody-induced platelet activation.

HIT is caused by platelet-activating immunoglobulin G (IgG) antibodies that bind to multimolecular complexes of cationic platelet factor 4 (PF4)—a member of the CXC subfamily of chemokines—bound to (anionic) heparin through electrostatic interactions.[2,3] Although anti-PF4/heparin antibodies are frequently triggered by heparin therapy, relatively few patients develop clinically evident HIT. Indeed, a major current problem with HIT is its "overdiagnosis"[4]: only 5% to 15% of patients who are referred for antibody testing have a serologic profile that supports a diagnosis of HIT.[5] The challenge for the clinician is to discern which of the (many) patients who develop thrombocytopenia in association with heparin therapy have HIT, a conundrum magnified by the observation that at most 50% of anti-PF4/heparin antibody-positive patients have "true" HIT, as indicated by the presence of platelet-activating IgG antibodies.[5]

EPIDEMIOLOGY

Table 131.1 lists risk factors for HIT. Patients at highest risk for HIT are those with multiple interacting risk factors (e.g., females given postoperative thromboprophylaxis with UFH for 2 weeks [frequency approximately 5%]).[6] Even higher frequencies (approximately 10%) are reported in patients with ventricular assist devices who are receiving therapeutic doses of UFH. Ironically, even though the risk for HIT appears to be somewhat higher in women (odds ratio, 1.5 to 2.0),[6] HIT is rare in pregnancy, particularly with the use of low-molecular-weight heparin (LMWH). The synthetic antithrombin-binding sulfated pentasaccharide, fondaparinux, although similarly immunizing as LMWH, is much less likely than LMWH to cause HIT, likely because fondaparinux does not usually increase the platelet-activating potential of HIT antibodies.[7] Indeed, fondaparinux is an effective treatment for HIT (discussed later).

Only a minority of patients who form anti-PF4/heparin antibodies following heparin treatment develop clinically evident HIT.[8] The proportion of antibody-positive patients who develop HIT ranges from as high as one-third (e.g., postorthopedic surgery thromboprophylaxis with UFH [nowadays rarely used for this indication]) to as few as 1 in 50 (postcardiac surgery patients).[9] Notably, the risk for HIT in postcardiac surgery patients who receive UFH thromboprophylaxis is only approximately 1% even though as many as 50% to 80% of patients develop detectable anti-PF4/heparin antibodies within 2 weeks of surgery.[10] In general, those at the highest risk for HIT are the subgroup of patients whose anti-PF4/heparin antibodies evince strong platelet-activating properties in vitro.[11] However, patient-dependent susceptibility factors are also important, because not all patients who form platelet-activating antibodies develop HIT.

PATHOBIOLOGY

Fig. 131.1 illustrates several features of HIT pathogenesis. Heparin binds reversibly and saturably to platelets and can weakly activate platelets in vitro through potentiation of $\alpha_{IIb}\beta_3$-mediated outside-inside signaling.[12] In general, the direct platelet-activating effects of heparin, as well as its immunogenicity, are proportional to its molecular mass and degree of sulfation, and associated ability to form ultra-large antigenic complexes, respectively; consequently, LMWH is less likely to cause HIT than UFH.[13] Antigen complexes are formed at relatively narrow PF4:heparin molar ratios, suggesting that immunization could reflect attainment of particular immunizing ratios of PF4 and heparin in vivo ("stoichiometric model of immunization").[14] A unique laboratory characteristic of HIT is that high heparin concentrations (10 to 100 units/mL) inhibit platelet activation by the pathogenic IgG[15,16]; this laboratory feature is exploited in diagnostic testing for HIT (see Diagnosis). The high overall frequency of anti-PF4/heparin immunization could reflect innate immunity, given that PF4/heparin ultra-large antigenic complexes bind to "natural" IgM in blood, activating the classical pathway of complement, with the complement-coated PF4/heparin/IgM complexes binding to B-cells via the complement receptor CD21, triggering the immune response.[17]

Platelet activation by HIT antibodies occurs because of platelet-activating HIT-IgG cross-link platelet FcγIIa receptors.[18] This leads to "strong" platelet activation, including the formation of procoagulant platelet-derived microparticles.[19] However, the high thrombotic risk of HIT likely reflects "pancellular" activation beyond platelets alone.[20,21] This includes HIT antibody-induced activation of endothelium and monocytes (with cell surface expression of tissue factor)[22,23] and activation of neutrophils (including resulting "netosis").[24,25] Moreover, injured vessels release von Willebrand factor (vWF) "strings" to which PF4 binds, resulting in additional platelet activation through interaction with HIT antibodies.[26]

The pancellular activation results in excess thrombin generation, which contributes to the pathogenesis of some of the unusual sequelae of HIT, which can include thrombosis involving large veins and arteries, as well as microvascular thrombosis (e.g., warfarin-associated venous limb gangrene.[27] HIT can also be complicated by overt (decompensated) disseminated intravascular coagulation (DIC).[28]

There is a characteristic timeline that underlies the HIT immune response (Fig. 131.2).[29,30] Formation of pathogenic IgG antibodies is surprisingly fast (detectable 4 to 5 days following initial heparin administration), even in patients who have never previously been exposed to heparin. Bacterial cell walls, which are negatively charged, bind PF4, and there is evidence that bacterial infection could be responsible for preimmunization against PF4-dependent antigens.[31] This could explain both the high frequency of anti-PF4/heparin immunization and of clinical HIT (i.e., HIT could represent a misdirected antibacterial immune response).[31] Although heparin-treated

Figure 131.1 PATHOGENESIS OF HEPARIN-INDUCED THROMBOCYTOPENIA: PANCELLULAR ACTIVATION. Heparin produces mild platelet activation, resulting in the release of platelet factor 4 (PF4) from platelet α-granules and the formation of immunogenic PF4/heparin complexes, including ultralarge complexes (ULCs). The ULCs also are recognized by natural IgM (shown in its pentameric form), which activate complement via C1q (not shown), that is, the classical complement pathway; the resulting PF4/heparin/IgM/C3 complexes bind to B lymphocytes via CD21 (complement receptor 2). B lymphocytes generate immunoglobulin G (IgG) antibodies that recognize the PF4/heparin complexes, which—if platelet-activating—are known as heparin-induced thrombocytopenia (HIT) antibodies; the Fc "tails" of the IgG bind to platelet FcγIIa receptors, resulting in Fc receptor clustering and consequent "strong" platelet activation. Platelet-derived microparticles are generated that accelerate thrombin generation. The HIT antibodies also recognize PF4 bound to endothelial heparan sulfate, leading to immunoinjury that causes endothelial activation, including the release of tissue factors. HIT antibodies also activate monocytes to generate tissue factors. Recent studies indicate that HIT antibody-induced neutrophil activation results in "netosis", that is, formation of neutrophil extracellular traps, contributing to immunothrombosis. Platelet-neutrophil and endothelial-neutrophil interactions are mediated through P-selectin. HIT antibodies also recognize PF4 bound to von Willebrand factor (vWF) "strings" released at sites of arterial injury, also contributing to localized platelet activation. All these events contribute to the "pancellular" activation underlying the prothrombotic diathesis of HIT.

TABLE 131.1 **Risk Factors for Heparin-Induced Thrombocytopenia**

Heparin type	Unfractionated > low-molecular-weight heparin > fondaparinux
Patient type	Postoperative (major > minor surgery) > medical > obstetric/pediatric
Dose[a]	Prophylactic dose > therapeutic dose > flushes
Duration	11–14 days[b] > 5–10 days > 4 days or fewer
Sex	Female > male

[a] Importance of heparin dose is uncertain because of confounding effect of patient type (e.g., postoperative patients tend to receive prophylactic-dose heparin whereas medical patients [e.g., with venous thromboembolism] are more likely to receive therapeutic-dose heparin); nevertheless, reported frequencies of heparin-induced thrombocytopenia (HIT) are relatively high in patients given postoperative prophylactic-dose heparin.

[b] Heparin exposure beyond 14 days does not usually increase the risk of HIT beyond that of an 11- to 14-day exposure.

patients can form heparin-dependent antibodies of the IgM or IgA subclass, these appear unlikely to cause HIT.[8]

As noted, thrombocytopenia develops in only a minority of patients who form HIT antibodies.[1] The variable risk for HIT in different patient populations may reflect variations in the susceptibility of platelets to activation by HIT-IgG and/or differences in the levels and immunoglobulin class composition of HIT antibodies. Poorly defined clinical factors also influence the risk for HIT, which occurs more often in surgical patients than in medical or obstetric patients.[6,32] Major trauma was more likely than minor trauma to be associated with HIT antibody formation and clinical HIT in one study.[33] There is indirect evidence that the formation of stoichiometrically optimal complexes of PF4/heparin influences the risk for immunization.[14] The clinical situation influences the type of HIT-associated thrombosis: venous thromboembolism typically develops in orthopedic patients with HIT, whereas thrombosis develops equally often in arteries and veins in cardiovascular patients with HIT.[1,32] Genetic factors likely play a role, too: HIT-associated thrombosis is more likely to occur in patients who bear the arginine (R) allele within a platelet Fc receptor polymorphism (H131R),[32,34,35] perhaps because this allele better allows for endogenous IgG2 subclass antibodies to inhibit the interaction of HIT antibodies with Fc receptors.

CLINICAL AND LABORATORY MANIFESTATIONS

Most patients with HIT have moderate thrombocytopenia; The median platelet count nadir is approximately 60 to 70 × 10^9/L; for 90% of patients, the platelet count nadir is greater than 20 × 10^9/L (Fig. 131.3).[32,36] In the rare patient whose platelet count falls to less than 10 × 10^9/L, there is often evidence of overt DIC, and red cell fragments and circulating normoblasts may be evident on examination of the blood smear. Thrombosis can occur in HIT patients even if there is a minimal decrease in the platelet count, and even if the platelet count nadir never falls below 150 × 10^9/L.[1,36] Neutrophil counts have also been reported to be elevated in patients with HIT, particularly those who develop thrombotic complications.[37]

The platelet count fall usually begins 5 to 10 days after the initiation of an immunizing heparin exposure and while the patient continues to receive heparin (typical-onset HIT).[38] Usually the immunizing trigger is heparin given during surgery (e.g., cardiac or vascular surgery) or that is started soon after surgery (e.g., postoperative thromboprophylaxis). Interestingly, starting LMWH thromboprophylaxis before elective surgery (as is more frequently done in Europe) is less likely to be associated with antibody formation compared with postoperative first-dose administration.[14]

HIT is recognized in approximately one-quarter of patients when the platelet count fall occurs abruptly after restarting UFH or LMWH (rapid-onset HIT). Invariably, such patients have been exposed to heparin within the previous 5 to 100 days, because HIT antibodies are transient and are only detectable for several weeks after an immunizing heparin exposure.[38] Consequently, rapid-onset HIT, which is caused by the administration of heparin to a patient with preformed HIT antibodies, is strongly associated with recent heparin exposure.

HIT is a highly prothrombotic condition (relative risk for thrombosis, ~15)[39]: Approximately 40% to 70% of HIT patients (with diagnosis confirmed by both PF4-dependent immunoassay and platelet activation assay) develop thrombosis.[32,36,40] Both venous (deep vein thrombosis and/or pulmonary embolism) and arterial (especially aortic and iliofemoral arterial thrombosis, ischemic stroke, or myocardial infarction) thrombosis can occur (venous:arterial thrombosis ratio, ~4:1).[32,40] Other complications include cerebral venous sinus thrombosis,[41] necrotizing skin lesions at the sites of subcutaneous heparin injection[42] and acute inflammatory/cardiorespiratory (anaphylactoid)[43,44] or transient memory disturbances after intravenous heparin bolus administration to sensitized persons.[45] Unexplained abdominal/flank pain or hypotension in a patient with HIT suggests adrenal infarction (often with associated adrenal hemorrhage), which if bilateral can lead to acute adrenal failure; the adrenal necrosis results from adrenal vein thrombosis.[46,47] Bowel infarction secondary to mesenteric artery thrombosis or mesenteric/portal vein thrombosis has also been reported.

Patients with HIT have an unusual predisposition to develop ischemic limb necrosis. Indeed, approximately 2% to 5% of such patients develop some degree of limb necrosis necessitating amputation. Historically, ischemic limb necrosis complicating HIT was linked to arterial thrombosis featuring platelet-rich clots.[48] However, microvascular thrombosis in a limb with deep-vein thrombosis, known as venous limb gangrene, is the most common explanation for ischemic limb loss in HIT.[27,49] Occasionally multiple limbs are involved. (See the box on Diagnostic Considerations in the Patient With Limb Ischemia and Thrombocytopenia.[50–53])

AUTOIMMUNE HIT

Recently, the term “autoimmune HIT” (aHIT) has been introduced into the HIT lexicon (Table 131.2).[54] The unifying concept is the detectability of HIT antibodies that activate platelets strongly in vitro

TABLE 131.2 **Autoimmune Heparin-Induced Thrombocytopenia Syndromes**

aHIT Syndrome	Definition
Delayed-onset HIT	HIT-related platelet count fall that begins or worsens after stopping heparin
Persisting HIT	HIT-related platelet count fall that requires prolonged time for platelet count recovery (at least 1 week[a])
Heparin “flush” HIT	HIT triggered by exposure only to small concentrations (“flushes”) of heparin
Spontaneous HIT syndrome	HIT without proximate heparin exposure; patients often have knee replacement surgery (without heparin exposure) or preceding infection
Fondaparinux-associated HIT	HIT caused by fondaparinux (most such patients have aHIT antibodies that further enhance platelet activation in the presence of fondaparinux (“cross-reactivity”)
Severe HIT with overt DIC	Some patients with severe HIT (marked thrombocytopenia, multiple thrombi, and/or overt DIC) who do not meet the above 5 definitions of aHIT have detectable aHIT antibodies

[a] No accepted definition, but platelet count recovery time exceeding 1 or 2 weeks suggests the diagnosis of “persisting” HIT (also known as “refractory” HIT).

aHIT, Autoimmune Heparin-Induced Thrombocytopenia; *DIC*, disseminated intravascular coagulation; *HIT*, heparin-induced thrombocytopenia.

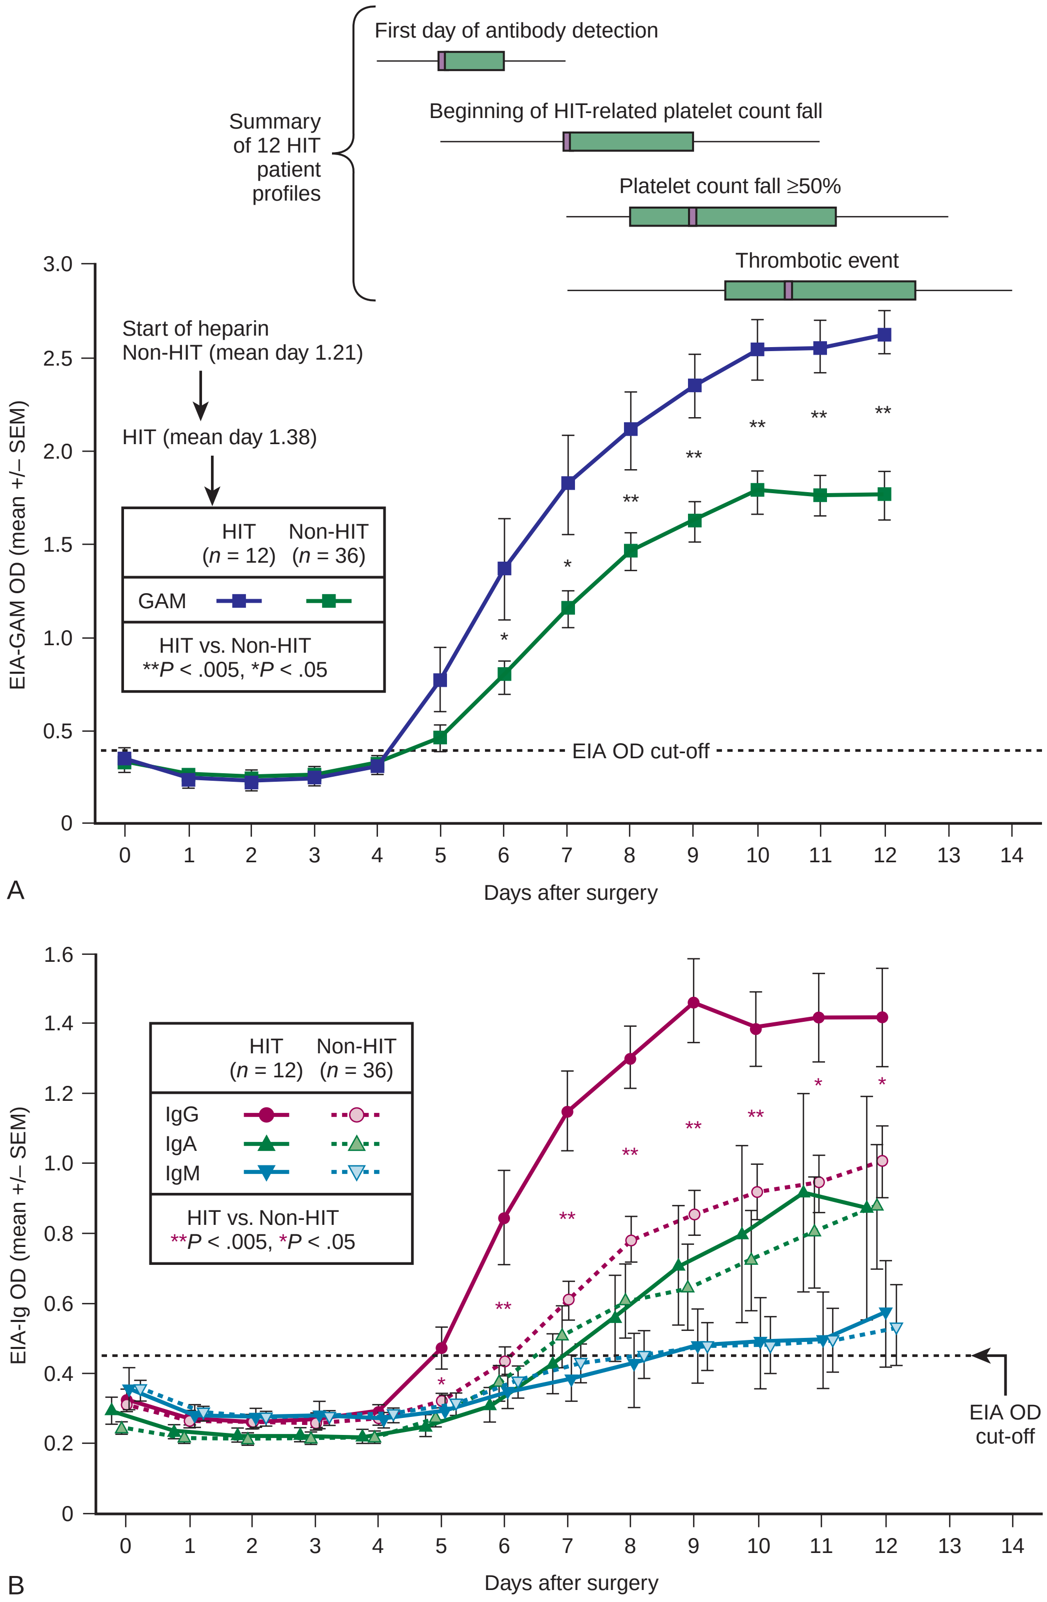

Figure 131.2 CHARACTERISTIC TIMELINE OF HEPARIN-INDUCED THROMBOCYTOPENIA. Anti-platelet factor 4 (PF4)/heparin antibodies (by enzyme immunoassay [EIA]) per postoperative day in 12 patients with heparin-induced thrombocytopenia (HIT) and 36 seropositive non-HIT control patients. (A) Mean (± standard error of the mean [SEM]) optical density (OD) of anti-PF4/heparin antibodies detected using a commercial immunoassay (EIA-GAM) that detects antibodies of all three immunoglobulin classes (IgG, IgA, IgM). HIT patients are indicated by blue squares and seropositive non-HIT controls by green squares. On each day beginning on postoperative day 6, there is a significant difference in the mean of the OD levels between the patients with HIT and the seropositive non-HIT controls ($P < .05$ by nonpaired t-test). At the top of the figure, summary data for 12 HIT patient profiles are shown for four key events (the first day of antibody detection, beginning of HIT-related platelet count fall, platelet count fall ≥50%, and thrombotic event), summarized as median (small purple squares within rectangles), interquartile range (rectangles), and range (ends of thin black lines). (B) Mean (±SEM) OD values of anti-PF4/heparin antibodies detected using an in-house immunoassay (EIA-Ig) that detects antibodies of the individual immunoglobulin classes, IgG (*red circles*), IgA (*green triangles*), and IgM (*blue inverted triangles*) for HIT (*solid symbols*) and non-HIT (*open symbols*). On each postoperative day beginning on day 5, there is a significant difference in the mean of the OD units for the IgG immunoassay between the patients with HIT and the seropositive non-HIT controls (**$P < .005$ for days 6 to 10; *$P < .05$ for days 5, 11, and 12). *(Fro* *ood. 2009;113:4693.)*

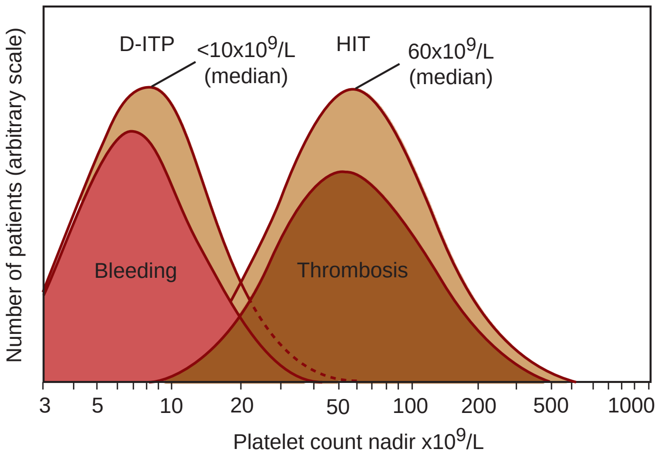

Figure 131.3 SEVERITY OF THROMBOCYTOPENIA IN DRUG-INDUCED IMMUNE THROMBOCYTOPENIA: A COMPARISON OF HEPARIN-INDUCED THROMBOCYTOPENIA VERSUS OTHER DRUG-INDUCED IMMUNE THROMBOCYTOPENIA DISORDERS. Whereas drug-induced immune thrombocytopenia (D-ITP) is strongly associated with petechiae and purpura, heparin-induced thrombocytopenia (HIT) is strongly associated with thrombosis. Note: The heights of the D-ITP and HIT curves are not drawn to scale, because HIT is more common than all DITP disorders combined. *(From Warkentin TE. Drug-induced immune-mediated thrombocytopenia—from purpura to thrombosis. N Engl J Med. 2007;356:891.)*

DIAGNOSTIC CONSIDERATIONS IN THE PATIENT WITH LIMB ISCHEMIA AND THROMBOCYTOPENIA

Concurrence of limb ischemia/necrosis and thrombocytopenia suggests one of several hematologic emergencies:

- HIT. Occlusion of large lower-limb arteries by platelet-rich “white clots” is characteristic of HIT. The major clue is an otherwise unexplained platelet count fall that begins 5 or more days after the initiation of heparin, with an absence of arterial pulses. Urgent thromboembolectomy may be limb-sparing.[50] Sensitive assays for HIT antibodies give strongly positive results. See subsequent entry for warfarin.
- Warfarin-induced phlegmasia cerulea dolens/venous limb gangrene. Coumarin anticoagulants, such as warfarin, can lead to venous ischemia (phlegmasia cerulea dolens) or venous limb gangrene in patients with DIC caused by HIT[27] or adenocarcinoma.[51] Limb loss can occur even though the limb pulses are palpable.
- Adenocarcinoma-associated DIC. Severe venous or arterial thrombosis can develop in patients with metastatic adenocarcinoma who have DIC.[51] This often occurs within hours after stopping heparin. A clinical clue is an otherwise unexplained rise in platelet count that occurs with initial or repeated heparin therapy.
- Sepsis-associated microvascular thrombosis. Acquired natural anticoagulant depletion (e.g., markedly reduced antithrombin or protein C levels), especially in the setting of acute ischemic hepatitis (“shock liver”), can complicate DIC associated with sepsis or cardiogenic shock, leading to bilateral acral limb ischemia or necrosis involving feet and (sometimes) fingers/hands (“symmetric peripheral gangrene”).[49,52] These patients can be misdiagnosed as having HIT. Optimal treatment is unknown but can include heparin anticoagulation (with anti-factor Xa monitoring), antithrombin concentrates, and plasma infusion.
- Septic embolism. Rarely, infective endocarditis or aneurysmal thrombosis leads to the constellation of thrombocytopenia and acute limb ischemia.
- Antiphospholipid syndrome. Autoimmune thrombocytopenia and hypercoagulability can interact to produce acute limb ischemia and thrombocytopenia in patients with antiphospholipid syndrome (particularly, catastrophic antiphospholipid syndrome, or CAPS).[53]

even in the absence of heparin; the clinical correlate is frequently that of a patient whose platelet count fall occurs or persists despite absence (or discontinuation of) heparin.

The first reported aHIT syndrome, “delayed-onset HIT,” indicates patients who develop thrombocytopenia that begins at least 5 days after a brief exposure to heparin or that worsens despite stopping heparin.[41,55] Sometimes, thrombocytopenia persists for several weeks despite stopping heparin (“persisting” or “refractory” HIT).[56,57] Other patients have developed HIT despite the sole exposure to heparin being heparin “flushes.”[58] On exceptionally rare occasions, a transient prothrombotic disorder that resembles HIT clinically and serologically occurs without any apparent preceding heparin exposure; triggers of so-called “spontaneous HIT syndrome” include knee replacement surgery (perhaps because of the release of heparin-like glycosaminoglycans from knee cartilage) and infection.[47,59–61] Some patients with fondaparinux-associated HIT have aHIT antibodies whose platelet-activating properties are enhanced in the presence of fondaparinux.[62] Finally, some patients with multiple venous and/or arterial thrombi, or who have unusually low platelet counts with DIC, have a laboratory picture of aHIT. aHIT syndromes are important to recognize, as they have certain treatment implications, including the efficacy of adjunctive therapy with high-dose IVIG.

DIFFERENTIAL DIAGNOSIS

Only approximately 10% of patients who undergo laboratory investigations for clinically suspected HIT have a serologic profile that supports the diagnosis (i.e., detectable heparin-dependent, platelet-activating IgG antibodies that recognize PF4/heparin complexes). The differential diagnosis includes postoperative thrombocytopenia (hemodilution/platelet consumption), thrombocytopenia of critical illness, and septicemia, among others. Some non-HIT disorders mimic HIT so closely that they warrant the term pseudo-HIT.[63] One example of pseudo-HIT is adenocarcinoma-associated DIC, in which the combination of progressive thrombocytopenia and severe venous limb ischemia/necrosis that occurs during the transitioning of patients from heparin (either UFH or LMWH) to warfarin may suggest a diagnosis of HIT.[51] Another disorder that can mimic HIT is the antiphospholipid syndrome: here, thrombocytopenia, thrombosis, and a false-positive PF4-dependent enzyme immunoassay (EIA) caused by anti-PF4 (not anti-PF4/heparin) antibodies can be present.[64] Recently, protamine (heparin)-induced thrombocytopenia as a potential explanation for post-cardiac surgery thrombocytopenia/thrombosis has been reported (see Chapter 130).

CLINICAL SCORING SYSTEMS

The pretest probability of HIT can be estimated using validated scoring systems. The 4Ts system represents a mnemonic that is based on ***T***hrombocytopenia, ***T***iming (of onset of thrombocytopenia or thrombosis), ***T***hrombosis (or other clinical sequelae of HIT), and no o***T***her explanation for thrombocytopenia, with each of the 4Ts scoring as an integer of 0, 1, or 2 points (thus the maximum score is 8 points) (Table 131.3).[65,66] The presence of platelet-activating HIT antibodies is unlikely (<3%) with a low score (≤3 points), but relatively probable (approximately 65%) with a high score (≥6). An intermediate score (4 or 5) indicates a clinical profile compatible with HIT, but also with other disorders, such as sepsis; here the frequency of platelet-activating HIT antibodies is still only approximately 10% to 20%.

Another scoring system is called the HIT Expert Probability (HEP) score (Table 131.4).[67] In the initial evaluation, a HEP score of 4 points or higher indicated an approximately 50% probability of HIT, whereas a score of 3 points or lower was associated with only a 3% probability of HIT.

It is unlikely that one scoring system offers major advantages over the other. In general, low scores in either system indicate a low

TABLE 131.3 **4Ts Scoring System: Estimating the Pretest Probability of Heparin-Induced Thrombocytopenia**

	Points (0, 1, or 2 for Each of Four Categories: Maximum Possible Score = 8)		
	2	**1**	**0**
Thrombocytopenia (acute)	Platelet fall >50% (nadir $\geq 20 \times 10^9$/L) and no surgery within preceding 3 days	Nadir, 10–19 × 10^9/L; or any 30%–50% fall; or, >50% fall within 3 days of surgery	Nadir, <10 × 10^9/L; or any <30% fall
Timing[a] of platelet count fall, thrombosis, or other sequelae	Clear onset between days 5–10; or $\leq$1 day (if prior heparin exposure in the past 5–30 days)	Consistent with day 5–10 fall, but not clear (e.g., missing platelet counts); or $\leq$1 day (heparin exposure within past 31–100 days); or platelet fall after day 10	Platelet count fall begins in $\leq$4 days without recent heparin exposure
Thrombosis or other clinical sequelae	New proven thrombosis; skin necrosis[b]; anaphylactoid reaction after IV heparin bolus; adrenal hemorrhage	Progressive or recurrent thrombosis; erythematous skin lesions[b]; suspected thrombosis (awaiting confirmation with imaging)	None
O***T***her cause for thrombocytopenia is not evident	No other explanation for platelet count fall is evident	Possible other cause is evident	Definite other cause is present
Pretest probability score: 6–8 = HIGH; 4–5 = INTERMEDIATE; 0–3 = LOW			

The scoring system shown here has undergone minor modifications from previously published scoring systems.

[a] First day of immunizing heparin exposure is considered on day 0; immunizing heparin is usually that given during or soon after surgery (e.g., unfractionated heparin [UFH] during cardiac surgery is more immunogenic than UFH given during preceding acute coronary syndrome or with heart catheterization); the day the platelet count *begins* to fall is considered the day of onset of thrombocytopenia.

[b] Skin lesions occurring at heparin injection sites.

probability of HIT, whereas high scores indicate approximately a 50 : 50 chance of HIT. Thus laboratory testing is crucial to establishing a diagnosis of HIT.

LABORATORY DIAGNOSIS

Assays for HIT antibodies can be classified as platelet "activation" (or "functional") and PF4-polyanion "antigen" assays (or immunoassays).[68] Activation assays that measure serotonin release from ^{14}C-labeled, washed platelets (i.e., the serotonin-release assay [SRA]) are quite sensitive and specific for detecting clinically significant HIT antibodies.[11,15,16] Important quality control maneuvers include the selection of platelet donors whose platelets respond well to Fc receptor stimulation, as well as the inclusion of negative and positive HIT sera of variable reactivity to ensure that the test platelets identify weaker HIT sera.[69] The characteristic activation profile produced by HIT serum includes increased platelet activation at low heparin concentrations (0.05 to 0.3 units/mL), but low background platelet activation at high heparin concentrations (10 to 100 units/mL).[15,16] Strong platelet activation induced by HIT sera even in the absence of pharmacologic heparin is a feature of delayed-onset HIT and other aHIT syndromes.[54,55]

Recently, the concept of "SRA-negative HIT" has been posited.[70,71] Such patients can be identified by using a PF4-enhanced platelet activation assay, such as the PF4-SRA (where high concentrations of PF4 are added, rather than heparin)[72] or the P-selectin expression assay.[73] One of these tests should be performed when the SRA gives an unexpected negative result in an immunoassay-positive patient who otherwise appears likely to have HIT.

Three enzyme(-linked) immuno(sorbent) assays (EIAs or ELISAs) are commercially available for detecting antibodies that recognize PF4 bound to heparin, to the polyanion, polyvinyl sulfonate, or PF4 (from platelet lysate) bound to protamine. These assays are very sensitive for detecting HIT antibodies but are much more likely than washed platelet activation assays to detect clinically insignificant anti-PF4/heparin antibodies. Thus results of laboratory tests must be interpreted in the clinical context—that is, HIT is a "clinicopathologic" syndrome.[74]

Activation and antigen assays are not 100% concordant, and there are advantages if reference laboratories are able to perform both types of assay. In general, serum or plasma from patients with clinical HIT has strongly positive assay results, whereas clinically insignificant antibodies give weaker results.[5] Indeed, if the EIA yields only a weakly positive result (e.g., 0.40 to 1.0 absorbance units), the corresponding probability of "true" HIT is 5% to 10% at most. In contrast, if the EIA yields a strongly positive result (>2.0 units), the probability of HIT exceeds 90%.[5]

One conceptual way to relate activation and antigen assays is through the "iceberg" model (Fig. 131.4), where a positive platelet activation assay better predicts for clinically relevant antibodies (the portion of iceberg above the waterline). Recently, the iceberg model has been adapted for rapid immunoassays (discussed subsequently).[75]

Rapid HIT immunoassays provide results within an hour of sample acquisition. Five rapid immunoassays are available depending on jurisdictional approval and local availability (Table 131.5). One assay, the latex immunoturbidimetric assay (LIA), is a functionalized immunoassay, as it detects HIT antibodies through competitive inhibition of a HIT-like monoclonal antibody.[76] Another assay, the chemiluminescence immunoassay (CLIA), is IgG-specific, and has a very good overall sensitivity-specificity profile.[77] Another assay, the lateral flow-immunoassay (LFI), is usually interpreted qualitatively (positive/negative), although if read by a scanner, a strong-positive result points to a high likelihood of clinically relevant antibodies being present.[78] The particle gel immunoassay (PaGIA), which uses blood bank methodology, is another qualitative assay that can, however, be modified to a semiquantitative assay by determining the titer of a positive result.[79] Finally, a recent systematic review/meta-analysis of the particle immunofiltration assay (PIFA) showed the assay to provide little diagnostic information, and its use is not recommended.[80] As a general rule, assays with relatively high sensitivity for HIT (PaGIA, LFI, CLIA, LIA) are useful for ruling out the diagnosis, especially in low or intermediate probability situations. In contrast, a positive rapid immunoassay points broadly to a 50-50 probability of HIT in most clinical circumstances.

TABLE 131.4 **Heparin-Induced Thrombocytopenia Expert Probability Scoring System**

Clinical Feature	Score
1. Magnitude of fall in platelet count (measured from peak platelet count to nadir platelet count since heparin exposure)	
a. <30%	–1
b. 30%–50%	1
c. >50%	3
2. Timing of fall in platelet count	
For patients in whom typical-onset HIT is suspected	
a. Fall begins <4 days after heparin exposure	–2
b. Fall begins 4 days after heparin exposure	2
c. Fall begins 5–10 days after heparin exposure	3
d. Fall begins 11–14 days after heparin exposure	2
e. Fall begins >14 days after heparin exposure	–1
For patients with previous heparin exposure in the last 100 days in whom rapid-onset HIT is suspected	
f. Fall begins <48 h after heparin reexposure	2
g. Fall begins >48 h after heparin reexposure	–1
3. Nadir platelet count	
a. $\leq 20 \times 10^9$/L	–2
b. $>20 \times 10^9$/L	2
4. Thrombosis (Select no more than one)	
For patients in whom typical-onset HIT is suspected	
a. New VTE or ATE ≥4 days after heparin exposure	3
b. Progression of preexisting VTE or ATE while receiving heparin	2
For patients in whom rapid-onset HIT is suspected	
c. New VTE or ATE after heparin exposure	3
d. Progression of preexisting VTE or ATE while receiving heparin	2
5. Skin necrosis	
a. Skin necrosis at subcutaneous heparin injection sites	3
6. Acute systemic reaction	
a. Acute systemic reaction after intravenous heparin bolus	2
7. Bleeding	
a. Presence of bleeding, petechiae, or extensive bruising	–1
8. Other causes of thrombocytopenia (Select all that apply)	
a. Presence of a chronic thrombocytopenic disorder	–1
b. Newly initiated nonheparin medication known to cause thrombocytopenia	–2
c. Severe infection	–2
d. Severe DIC (defined as fibrinogen <100 mg/dL and D-dimer >5.0 μg/mL	–2
e. Indwelling intraarterial device (e.g., IABP, VAD, ECMO)	–2
f. Cardiopulmonary bypass within previous 96 h	–1
g. No other apparent cause	3

In its initial evaluation, a HEP score of ≥4 points indicated an approximately 50% probability of HIT, whereas a score of ≤3 points was associated with only a 3% probability of HIT.

ATE, Arterial thromboembolism; *DIC*, disseminated intravascular coagulation; *ECMO*, extracorporeal membrane oxygenation; *HIT*, heparin-induced thrombocytopenia; *IABP*, intraaortic balloon pump; *VAD*, ventricular assist device; *VTE*, venous thromboembolism.

However, for those rapid immunoassays that provide semiquantitative output, a strong-positive result points to a positive diagnosis of HIT in the appropriate clinical context;[76,77] this is analogous to a patient with a strong-positive EIA result (e.g., >2.0 OD units). Recently, the combined use of two rapid immunoassays—PaGIA and CLIA,[81] or LIA and CLIA[82]—have been reported. Fig. 130.4 shows how data can be interpreted with the results of dual LIA/CLIA testing.

PROGNOSIS

Approximately half of all patients with SRA-positive HIT have clinically evident thrombosis at the time of initial diagnosis of HIT.[40] Among patients without thrombosis at diagnosis, there appears to be at a high risk (approximately 25% to 50%) for subsequent thrombosis if heparin is simply discontinued.[40] It is increasingly accepted

Figure 131.4 ICEBERG MODEL OF HEPARIN-INDUCED THROMBOCYTOPENIA (HIT). The part of the iceberg that protrudes above the waterline indicates patients with HIT±T (HIT with or without thrombosis). The large iceberg represents the totality of antibodies detected by polyspecific PF4-dependent EIA (EIA-IgG/A/M), with a large subgroup comprising patients with detectable PF4-reactive antibodies of IgG class (EIA-IgG). The great majority of HIT cases are detected by serotonin-release assay (SRA), yielding SRA-positive (SRA+) results, and with most SRA-negative HIT detectable by a modified (PF4-enhanced) SRA, either the PF4-SRA or the PF4/H-SRA (collectively indicated as "PF4(±H)-SRA"). The latex immunoturbidimetric assay (LIA) and chemiluminescence-immunoassay (CLIA) both have relatively high sensitivity for HIT, with the CLIA (an IgG-specific immunoassay) correlating more closely with EIA-IgG than the LIA (which can also detect IgA and IgM class antibodies). Although the model implies 100% sensitivity of the EIA-IgG and EIA-IgGAM, in reality, an occasional HIT case will be negative in one commercial EIA but test positive in another. The model also indicates that the probability of HIT increases with increasing reactivity by EIA or by LIA and/or CLIA (including interpreting both tests together). For the 6-point scale, 0, 1, 2, or 3 points, respectively, are given for LIA and CLIA results that are <1.00, 1.00–4.99, 5.00–15.99, and ≥16.00. Note that "Probability of platelet-activating antibodies" refers to the probability of a sample testing positive by any platelet activation assay (e.g., conventional SRA, PF4-SRA, or PF4/H-SRA). *(From Warkentin TE. How I diagnose and manage HIT. Hematology Am Soc Hematol Educ Program. 2011;2011:143–149.)*

that further anticoagulation is indicated in most patients strongly suspected as having "isolated" HIT—that is, HIT recognized because of thrombocytopenia rather than because of HIT-associated thrombosis. Indeed, it is a recommendation of the American Society of Hematology (ASH) guidelines to give therapeutic-dose anticoagulation for isolated HIT.[83]

THERAPY

Although it is standard practice to discontinue heparin in patients strongly suspected of having HIT, including stopping heparin "flushes" of intravascular catheters (with substitution of saline flushes), heparin cessation is not necessarily beneficial, for two reasons: (1) heparin likely has an anticoagulant effect even in patients with HIT, and (2) HIT antibodies often cause ongoing platelet activation and hypercoagulability in the absence of pharmacologic heparin. In addition, HIT antibody levels can decline even with continued heparin.[84] The recognition that patients with HIT have increased thrombin generation[27] provides a rationale for the use of nonheparin anticoagulant agents that rapidly inhibit thrombin or its generation.

Currently, there are two types of anticoagulant therapeutic approaches that are used to treat HIT: (1) exclusive or predominant factor Xa inhibitors, either parenteral "indirect" (i.e., antithrombin-dependent) factor Xa inhibitors (danaparoid, fondaparinux) or "direct" factor Xa inhibitors (rivaroxaban, apixaban), and (2) DTIs (argatroban, bivalirudin, dabigatran). In the author's opinion, factor Xa inhibitors—although not approved in the United States for treatment of HIT—are the preferred treatment option for HIT, because they have numerous advantages over DTIs (Table 131.6). In addition, because approximately 90% of patients suspected of HIT do not have HIT,[5] another advantage for factor Xa inhibitors is that these agents, unlike "niche" DTIs such as argatroban and bivalirudin, are safe and effective for the prevention and treatment of thrombosis in numerous non-HIT settings. Another recent conceptual development in HIT treatment is the growing recognition that platelet activation can be rapidly inhibited by the administration of high-dose IVIG, making this a rational adjunctive treatment in several clinical situations.

TABLE 131.5 Rapid Immunoassays for Heparin-Induced Thrombocytopenia

Rapid Immunoassay	Comments
Latex immune-turbidimetric assay (LIA)	Functionalized immunoassay (see text); high sensitivity and moderate specificity; semiquantitative assay (result in U/mL); performed on coagulation instrument (requires plasma); available in the United States
Chemiluminescence immunoassay (CLIA)	High sensitivity and high specificity; detects IgG class antibodies; semiquantitative assay (result in U/mL); available in the United States
Particle gel immunoassay (PaGIA)	High sensitivity and moderate specificity; semiquantitative assay (if performed using diluted serum); not available in the United States
Lateral flow immunoassay (LFI)	High sensitivity and moderate specificity; semiquantitative assay (if read using a scanner); not available in the United States
Particle immunofiltration assay (PIFA)	Poor sensitivity and specificity (not recommended for use); qualitative results only (positive/negative); no longer available in the United States

High sensitivity generally means at least 90%–95%; moderate specificity for most assays indicates a positive predictive value (PPV) of approximately 50% overall irrespective of pretest probability; however, PPV can approach 100% if the test result is strongly positive (e.g., LIA or CLIA >16 U/mL; positive PaGIA at 1 in 16 dilution.

Indirect Factor Xa Inhibitors: Danaparoid and Fondaparinux

Danaparoid is an anticoagulant heparinoid (mixture of glycosaminoglycans) with predominant inhibitory activity against factor Xa that is effective for treating HIT; however, danaparoid was never approved for HIT treatment in the United States (although it was approved in many other countries, including Canada and the European Union) and was discontinued in the United States in April 2002. Danaparoid was shown to be safe and effective for the treatment of HIT in an open-label randomized controlled trial (vs. dextran 70)[85] and in a retrospective comparison against ancrod (defibrinogenating snake venom) and/or vitamin K antagonist therapy.[86]

In recent years, however, physicians have increasingly used fondaparinux as an off-label therapy for HIT. The advantages of fondaparinux include its long half-life, the fact that it does not require coagulation monitoring nor does it influence the aPTT or international normalized ratio (INR), its low potential to cross-react with HIT antibodies, and low cost. In addition, because relatively few patients with suspected HIT actually have this diagnosis, the wide experience with fondaparinux and its approval for the prevention and treatment of thrombosis in non-HIT settings constitute other advantages. To date, the experience with fondaparinux to treat HIT has been favorable.[87–90] Also, fondaparinux is much less likely than UFH or LMWH to precipitate rapid-onset HIT in patients who have unrecognized HIT antibodies.[91] Although fondaparinux thromboprophylaxis has been associated with rare cases of de novo HIT,[62,92] this should not deter from its use as a treatment of HIT because the potential to trigger immunization is "dissociated" from whether an anticoagulant potentiates antibody-induced platelet activation,[7] and fondaparinux has low potential to "cross-react" with HIT antibodies and thus to exacerbate HIT[91] (although this phenomenon has been reported[56,60]). Dosing information for danaparoid and fondaparinux is shown in Table 131.7.

Indirect Factor Xa Inhibitors: Rivaroxaban, Apixaban, Edoxaban

In theory, oral direct factor Xa inhibitors, such as rivaroxaban and apixaban, should be effective for the treatment of HIT. Indeed, anecdotal experience with rivaroxaban[46,60,93,94] and apixaban[93,95] has been generally favorable, and the ASH HIT treatment guidelines[83] include these direct oral anticoagulants (DOACs) as anticoagulant options for treating HIT. Dosing for two oral Xa inhibitors is shown in Table 131.8.

Direct Thrombin Inhibitors: Bivalirudin, Argatroban

Bivalirudin (Angiomax) is a 20-amino-acid thrombin inhibitor modeled after hirudin (natural anticoagulant produced by the medicinal leech) that is composed of two peptide fragments that recognize the active site of thrombin and its fibrinogen-binding site, linked by a tetraglycine spacer.[96] The half-life of bivalirudin is about 25 minutes, and only minor dose adjustments are needed in patients with renal insufficiency because bivalirudin is only partially cleared by the kidneys. It is approved as an alternative to heparin in patients undergoing percutaneous coronary intervention (PCI), including those with HIT.[97] Its short half-life and predominantly extrarenal elimination are reasons why it is an option for intraoperative anticoagulation in patients undergoing cardiac surgery when heparin is contraindicated because of acute or recent HIT. Published experience using bivalirudin off-label to treat HIT appears favorable.[98]

Argatroban (marketed as Argatroban in the United States and as Novastan elsewhere) is a small-molecule (527-Da) DTI that undergoes predominantly hepatobiliary excretion and is, therefore, suitable for use without dose adjustment in patients with renal failure (the dose is reduced by three-quarters in patients with hepatic insufficiency).[99] Argatroban is approved in the United States for both treatment and prevention of thrombosis in HIT. It is given in the same dosage for both indications (usual starting infusion rate of 2 μg/kg/min without an initial bolus). However, lower starting doses are usually given (e.g., 0.5 to 1.2 μg/kg/min), especially in critically ill patients.[100] Argatroban (in substantially higher doses) is also approved for anticoagulation during PCI in patients with acute HIT or a history of HIT.[101] Its half-life is 40 to 50 minutes. Argatroban prolongs the INR more than bivalirudin,[102] and a higher-than-usual target INR during warfarin co-therapy[103] (which depends on the thromboplastin reagent used to measure the INR) can be expected (see the section on Caveats in Treatment of Heparin-Induced Thrombocytopenia). Argatroban reduced the frequency of a composite endpoint (new thrombosis, limb amputation, and all-cause mortality) from 56.5% (in historical controls) to 43.8% and 41.5% in two studies of patients with HIT complicated by thrombosis; new thrombosis event rates were reduced from 34.8% to 19.4% and 13.1%, respectively.[104] In patients with isolated HIT, argatroban reduced the rate of new thrombosis from 22.4% to 6.9%, and the combined event rate of new thrombosis, limb amputation, and all-cause mortality from 38.8% to 26.9%.[104] Unfortunately, outcome data are not available for the subgroup of argatroban-treated patients who tested positive for HIT antibodies; thus, the comparison with (antibody-positive) historical controls may overestimate any benefit with argatroban (antibody status unknown). Dosing information for the parenteral DTIs, bivalirudin and argatroban is shown in Table 131.9.

In theory, dabigatran, an oral thrombin inhibitor, should also be effective for the treatment of HIT. To date, experience in treating HIT has been minimal.

High-Dose Intravenous Immunoglobulin

Increased plasma IgG concentrations inhibit HIT antibody-induced platelet activation through FcγIIa receptors.[105] High-dose intravenous immunoglobulin (IVIG) is emerging as an approach to rapidly inhibit platelet activation, leading in most cases to rapid platelet

TABLE 131.6 **Comparison of the Three Classes of Anticoagulants Used to Treat Heparin-Induced Thrombocytopenia**

	Indirect (AT-Dependent) Factor Xa Inhibitors: Danaparoid, Fondaparinux	Direct Factor Xa Inhibitors: Rivaroxaban, Apixaban	Direct Thrombin Inhibitors: Argatroban, Bivalirudin
Half-life	✓ Long (danaparoid, 25 h[a]; fondaparinux, 17 h): reduces the risk of rebound hypercoagulability	✓ Intermediate (rivaroxaban, ~12 h[b]; apixaban, ~12 h): reduces the risk of rebound hypercoagulability	Short (<2 h): potential for rebound hypercoagulability
Dosing	✓ Both prophylactic- and therapeutic-dose regimens[c]	✓ Both prophylactic- and therapeutic-dose regimens[c]	Prophylactic-dose regimens are less well established
Monitoring	✓ Direct (anti-Xa levels): accurate drug levels obtained	✓ Direct (anti-Xa levels): accurate drug levels obtained (not widely available)	Indirect (aPTT): risk for DTI underdosing resulting from aPTT elevation caused by non-DTI factors, (e.g., HIT-associated DIC, liver dysfunction, etc.)
Effect on INR	✓ No significant effect: thus simplifies overlap with warfarin	✓ Increases with rivaroxaban; however, as rivaroxaban and apixaban can be used for long-term anticoagulation, no need for warfarin overlap	Increases INR: argatroban > bivalirudin; complicates warfarin overlap
Protein C pathway	✓ Adverse effect unlikely (thrombin remains available to activate protein C)	✓ Adverse effect unlikely (thrombin remains available to activate protein C)	Thrombin inhibition could impair thrombin-mediated activation of the protein C pathway
Reversibility of action	✓ Irreversible inhibition: AT forms a covalent bond with factor Xa	Reversible inhibition	Reversible inhibition
Efficacy and safety in non-HIT settings	✓ Treatment and prophylaxis of VTE (danaparoid, fondaparinux) and ACS (fondaparinux)	✓ Treatment and prophylaxis of VTE (rivaroxaban, apixaban), ACS (rivaroxaban), and chronic CAD or PAD (rivaroxaban)	Not established for most non-HIT settings (exception: bivalirudin established for PCI)
Platelet activation	✓ Danaparoid inhibits platelet activation by HIT antibodies	No effect	No effect
Inhibition of clot-bound factor Xa or thrombin	No effect	✓ Inhibition of both free and clot-bound factor Xa	✓ Inhibition of both free and clot-bound thrombin
Drug clearance	Predominantly renal	Renal component and metabolism (e.g., rivaroxaban and apixaban both metabolized by CYP3A4)	Predominantly hepatobiliary: argatroban; renal component: bivalirudin
Cost	✓ Relatively low[d] (fondaparinux)	✓ Relatively low[d]	Relatively high[d]

A check mark (✓) indicates favorable feature in comparison to drug classes (author's opinion).

[a] For danaparoid, half-lives of its anti-thrombin (anti-IIa) and its thrombin generation inhibition activities (2–4 h and 3–7 h, respectively) are shorter than for its anti-Xa activity (approximately 25 h).

[b] Mean terminal elimination half-life 5–9 h in the young but 11–13 h in the elderly.

[c] Although therapeutic dosing is recommended for HIT, the availability of prophylactic-dose regimens increases flexibility when managing potential non-HIT situations when diagnostic certainty is not high.

[d] Another cost consideration is that a patient can be discharged to home on subcutaneous danaparoid or fondaparinux, or oral rivaroxaban or apixaban, whereas an additional 5–7 in-hospital days may be required for parenteral DTI-warfarin overlap before discharge from hospital.

ACS, Acute coronary syndrome; *aPTT*, activated partial thromboplastin time; *AT*, antithrombin; *CAD*, coronary artery disease; *DIC*, disseminated intravascular coagulation; *DTI*, direct thrombin inhibitor; *HIT*, heparin-induced thrombocytopenia; *INR*, international normalized ratio; *PAD*, peripheral arterial disease; *PCI*, percutaneous coronary intervention; *VTE*, venous thromboembolism.

count increase and probable decrease in thrombotic risk (for review, see reference 106). Currently, high-dose IVIG is recommended as adjunctive therapy (together with therapeutic-dose anticoagulation) for treating aHIT disorders, such as delayed-onset HIT,[107] persisting (refractory) HIT,[108] heparin "flush" associated HIT,[109] or spontaneous HIT syndrome.[110] In addition, IVIG has been used prior to planned heparin reexposure in patients who continue to have circulating platelet-activating HIT antibodies.[111,112]

Caveats in Treatment of Heparin-Induced Thrombocytopenia

Warfarin and other vitamin K antagonists (coumarins) should not be used during the acute thrombocytopenic phase of HIT.[27] A particularly high-risk situation is HIT associated with deep vein thrombosis, especially if there is overt (decompensated) DIC. If such patients are treated with warfarin, there is a risk for progression to venous limb gangrene.[27,104] The laboratory marker for this unusual syndrome is a high INR (generally, greater than 4.0), which corresponds to the combination of a marked reduction in the level of protein C together with increased thrombin generation (as evidenced by elevated levels of thrombin-antithrombin complexes) during warfarin therapy.[27] Although warfarin (in theory) should be safe in a patient whose thrombin generation is controlled (e.g., using a DTI), it is important to delay the initiation of warfarin until there is a substantial resolution of the thrombocytopenia (to more than 150×10^9/L).[83,104] Warfarin treatment should be delayed because its prolongation of the aPTT may result in *underdosing* of the DTI, and because stopping the DTI before resolution of the HIT during warfarin overlap can lead to limb loss caused by fulminant venous limb gangrene.

Several case observations suggest that aPTT confounding of DTI therapy can be a factor explaining the progression of thrombosis in patients with severe HIT.[4,113] For example, patients can develop progressive thrombocytopenia and HIT-associated consumptive coagulopathy despite stopping heparin (Fig. 131.5). In such patients, aPTT

TABLE 131.7 Treatment Schedules for Danaparoid and Fondaparinux

Anticoagulant	Therapeutic Dosing Protocol for HIT-Associated Thrombosis[a]	Anticoagulant Monitoring	Clearance	Half-Life (h)	Comment
Danaparoid	Initial bolus, 2250 units[b] IV; accelerated infusion (400 units/h × 4 h, 300 units/h × 4 h; then 200 units/h IV, subsequently adjusted by antifactor Xa levels)	Antifactor Xa levels (target, 0.5–0.8 units/mL)	Renal (minor)	25	Widely approved for HIT treatment (although not in the United States); not available in the United States; low risk for in vivo cross-reactivity; prophylactic-dose therapy[c] may be appropriate when clinical suspicion for HIT is low
Fondaparinux	7.5 mg[d] subcutaneous once daily	Anti–Xa factor levels (target levels not well established)	Renal (major)	17	Not approved for HIT treatment (although increasingly used as off-label therapy). Prophylactic-dose therapy[e] may be appropriate when clinical suspicion for HIT is low, or if there is renal insufficiency

[a] Therapeutic dosing is usually appropriate for strongly suspected or confirmed HIT (including “isolated” HIT, i.e., HIT without apparent thrombosis), or when thrombosis is documented.

[b] Adjust IV danaparoid bolus for body weight: <60 kg, 1500 units; 60–75 kg, 2250 units; 75–90 kg, 3000 units; >90 kg, 3750 units.

[c] Prophylactic-dose regimen, 750 units subcutaneous every 8 h (for renal failure, reduce to 750 units every 12 h).

[d] Five milligrams for body weight <50 kg and 10 mg for body weight >100 kg; the author sometimes gives 10 mg as the first and/or second dose (rather than 7.5 mg) for severe HIT. Because HIT treatment is usually started in the afternoon, the author usually gives the second dose (and subsequent doses) at 8 AM (i.e., the interval between first and second doses is often only 14–20 h rather than 24 h), which helps to achieve steady-state therapy more quickly. Dose reduction and antifactor Xa monitoring (if available) are appropriate if being used in a patient with renal insufficiency.

[e] Prophylactic-dose regimen, 2.5 mg subcutaneous every day (assumes normal renal function).

HIT, Heparin-induced thrombocytopenia; *IV*, intravenous.

TABLE 131.8 Treatment Schedules for Rivaroxaban and Apixaban (Off-Label Treatment for Heparin-Induced Thrombocytopenia)

Anticoagulant	Therapeutic Dosing Protocol[a]	Anticoagulant Monitoring	Clearance	Half-Life (h)	Comment
Rivaroxaban	15 mg twice-daily p.o. for 21 days; then 20 mg once-daily p.o.[b]	Not generally required	33% renal	~12[c]	Use with caution if CrCl 15–29 mL/min; avoid if CrCl <15 mL/min or if coadministering dual inhibitors of CYP3A4 and P-glycoprotein
Apixaban	10 mg twice-daily p.o. for 7 days[d]; then, 5 mg twice-daily p.o.[b]	Not generally required	25% renal	~12[c]	Use with caution if CrCl 15–29 mL/min; avoid if CrCl <15 mL/min or coadministering dual inhibitors of CYP3A4 and P-glycoprotein

[a] Therapeutic dosing is usually appropriate for strongly suspected or confirmed HIT (including “isolated” HIT, i.e., HIT without apparent thrombosis), or when thrombosis is documented.

[b] Duration of anticoagulation is usually at least 3–6 months for patients with HIT-associated thrombosis, but for patients with isolated HIT, anticoagulation can generally be stopped once the platelet count has recovered to a stable plateau, and if no evidence for thrombosis or other indication for anticoagulation is apparent.

[c] The half-life of both rivaroxaban and apixaban is increased by 30%–50% in patients with CrCl 15–29 mL/min.

[d] Apixaban is given at a dose of 10 mg twice daily for 7 days in patients with acute venous thromboembolism, but it is reasonable to continue the higher dose for more than 7 days in patients with aHIT who have a persistently low platelet count (i.e., “persisting” or “refractory” HIT).

aHIT, Autoimmune heparin-induced thrombocytopenia; *HIT*, heparin-induced thrombocytopenia.

TABLE 131.9 Treatment Schedules for Bivalirudin and Argatroban

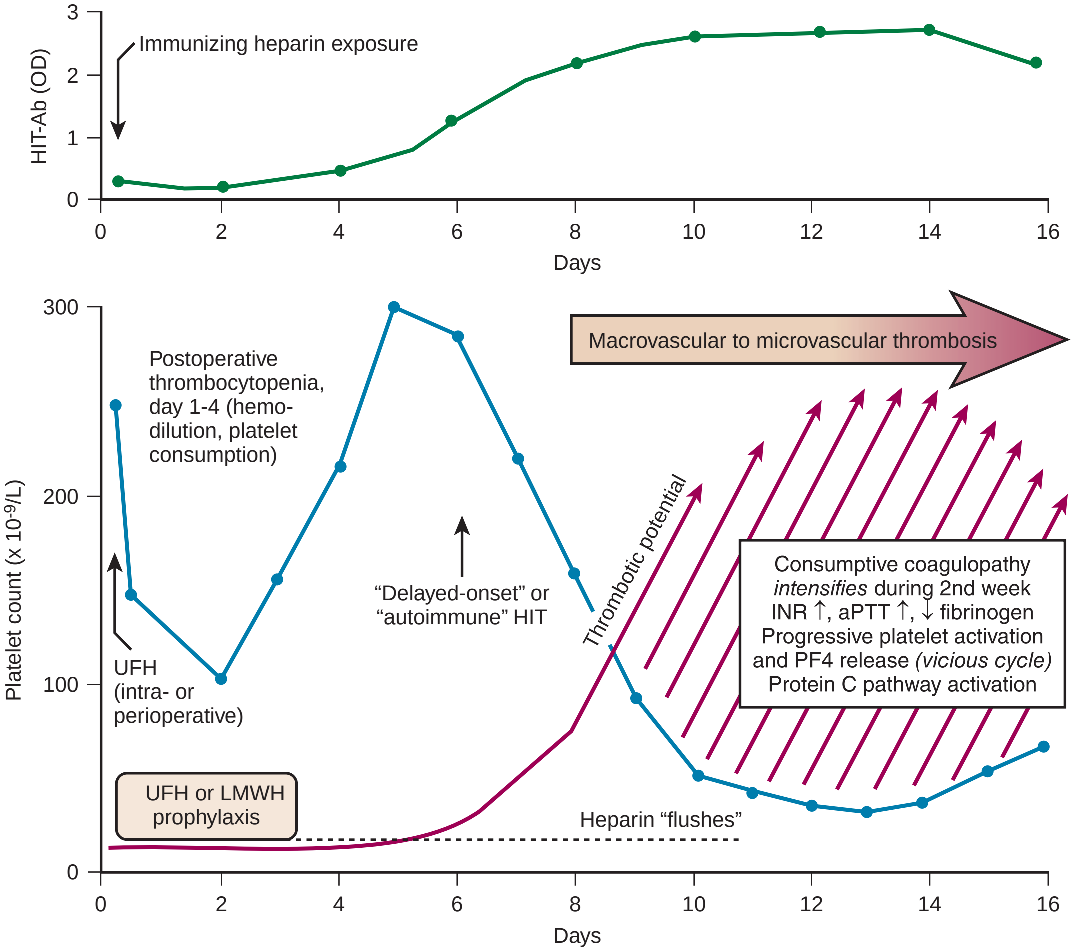
Anticoagulant	Dosing Protocol for HIT-Associated Thrombosis	Anticoagulant Monitoring[a]	Clearance	Half-Life (min)	Comment
Bivalirudin	No bolus; initial infusion rate: 0.15–0.20 mg/kg/h	1.5–2.5 × baseline aPTT	Enzymic (80%); renal (20%)	25	Off-label treatment for HIT (although approved for PCI in patients with HIT); minor prolongation of INR (compared with argatroban)
Argatroban	No bolus; initial infusion rate: 2 μg/kg/min	1.5–3.0 × baseline aPTT (maximum aPTT, 100 s)	Hepatobiliary	40–50	Initial dose 0.5 μg/kg/min in hepatic insufficiency[d]; moderate or marked prolongation of INR, which complicates overlap with warfarin anticoagulation

Dosing protocols shown are appropriate for most patients with strongly suspected or confirmed HIT whether or not complicated by thrombosis. (Dosing for bivalirudin and argatroban is substantially different when given for PCI.)

[a] In general, the patient’s baseline aPTT should be used for calculating target range, when appropriate; otherwise, the mean laboratory normal range can be used.

[d] Reduced initial dosing (e.g., 0.5–1.2 μg/kg/min) is also appropriate for patients in intensive care units, with cardiac failure, or early postcardiac surgery.

aPTT, Activated partial thromboplastin time; *HIT*, heparin-induced thrombocytopenia; *INR*, international normalized ratio; *PCI*, percutaneous coronary intervention.



Indirect (AT-mediated) factor Xa inhibitors (danaparoid, fondaparinux)	1. Long half-life achieves stable levels of anticoagulation. 2. No interference with activation of the protein C pathway. 3. Specific assays accurately measure drug levels (anti-Xa activity). 4. Inhibition of HIT-Ab-induced platelet activation (danaparoid only).
Direct thrombin inhibitors (DTIs) (hirudin, argatroban, bivalirudin)	1. aPTT monitoring can be unreliable, e.g., DIC, liver disease, warfarin. 2. Short half-lives — risk for "rebound" hypercoagulability. 3. Interfere with thrombin-induced activation of protein C pathway. 4. Reversible DTIs (argatroban, bivalirudin) could block thrombin inhibition by AT.
Vitamin K antagonists (warfarin, acenocoumarol, phenprocoumon)	1. Vitamin K antagonists do not inhibit thrombin or its generation. 2. Predispose to protein C depletion (vitamin K–dependent factor). 3. Raise the aPTT, thus risking DTI underdosing or interruption. 4. Long half-lives, thus any adverse effects could persist for days.

Figure 131.5 CONCEPTUAL FRAMEWORK OF HEPARIN-INDUCED THROMBOCYTOPENIA (HIT): FOCUS ON HEPARIN-INDEPENDENT PLATELET ACTIVATION AND DELAYED-ONSET ("AUTOIMMUNE") HIT. The *upper panel* shows the timeline of HIT antibody (HIT-Ab) formation, as judged by optical density units in an antiplatelet factor 4/polyanion enzyme immunoassay (EIA). The *middle panel* illustrates a platelet count decline in the absence of heparin (or with small amounts of heparin, e.g., heparin flushes) indicating delayed-onset HIT, with the intensification of HIT-associated hypercoagulability from day 7 to 14, especially after stopping heparin. Patients with this clinical profile often have HIT-associated consumptive coagulopathy (overt disseminated intravascular coagulopathy [DIC]) and are at risk for confounding of activated partial thromboplastin time (aPTT)–monitored direct thrombin inhibitor (DIT) treatment. The *lower panel* compares different classes of anticoagulants for expected effects on HIT-associated hypercoagulability, including the risk for aPTT confounding in the setting of HIT-associated DIC. *AT*, Antithrombin; *INR*, international normalized ratio; *LMWH*, low-molecular-weight heparin; *PF4*, platelet factor 4; *aPTT*, activated partial thromboplastin time; *UHF*, unfractionated heparin. *(From Warkentin TE. Agents for the treatment of heparin-induced thrombocytopenia. Hematol Oncol Clin North Am. 2010;24:755.)*

monitoring of DTI therapy can fail because a brief course of DTI can abruptly lead to supratherapeutic aPTT levels—not because of anticoagulant overdosing but because of the combination of DTI and consumptive coagulopathy—and interruption/cessation of DTI therapy can be associated with rapid progression of microvascular thrombosis. In this setting, factor Xa inhibitors (danaparoid, fondaparinux, rivaroxaban, apixaban) may be more effective because they do not require aPTT monitoring. Alternatively, DTI levels can be measured directly, but these assays are rarely performed in North American laboratories.

Using sensitive assays for HIT antibodies, LMWH reacts similarly to UFH in vitro. Furthermore, because LMWH can lead to worsening of clinical HIT, these agents should not be used to treat HIT.[83,104]

Although primary treatment for HIT should include an anticoagulant that inhibits thrombin or reduces its generation, certain treatment adjuncts can be used in special situations. These include surgical thromboembolectomy, high-dose IVIG (discussed above), antiplatelet drugs such as aspirin, and therapeutic plasma exchange.[114]

These caveats, along with recommendations for the management of patients with suspected HIT, are summarized in the box on Diagnosis and Treatment of Heparin-Induced Thrombocytopenia.

PLATELET COUNT MONITORING FOR HEPARIN-INDUCED THROMBOCYTOPENIA

The frequency of platelet count monitoring in patients receiving heparin should reflect the overall risk of HIT (i.e., the preparation, the dose, and the clinical situation).[83,104] At least alternate-day platelet count monitoring should be considered in patients at relatively high risk for developing HIT (e.g., after orthopedic or cardiac surgery). Monitoring at least two or three times a week should be considered for patients at moderate risk for developing HIT (e.g., medical patients receiving UFH, postoperative patients receiving LMWH). The frequency of HIT is low with LMWH,[1,6,13] particularly in medical patients or during pregnancy, and routine platelet count monitoring may not be required in such settings.[1,6] In addition, HIT rarely begins 14 or more days after the initiation of a course of heparin,[38] so routine monitoring beyond this period is not required.

ANTICOAGULATION AND PREVIOUS HEPARIN-INDUCED THROMBOCYTOPENIA

HIT antibodies are transient and usually are undetectable several weeks or a few months after an episode of HIT.[38] If HIT antibodies are no longer detected, it is appropriate to use heparin for a brief indication in situations where other anticoagulants have drawbacks, for example, cardiac surgery.[38,104,115,116] Heparin should be avoided preoperatively (e.g., argatroban or bivalirudin can be used for heart catheterization). The risk of recurrent HIT appears to be low (approximately 2%) but is possible beginning approximately one week post-reexposure for cardiac or vascular surgery even if postoperative heparin is not given, because of the possibility of regenerating strong HIT antibodies that can activate platelets in the absence of pharmacologic heparin.[116] Alternatively, if a patient with recent HIT remains SRA+ and heparin reexposure is desired (e.g., for urgent cardiac surgery), therapeutic plasma exchange can be used to remove HIT antibodies preoperatively; in this situation, achieving a negative SRA is the appropriate serologic endpoint (as the EIA can remain positive even when platelet-activating antibodies are no longer detectable by SRA).[114] Another option (favored by the author) is to give high-dose IVIG shortly prior to the planned surgery so that intraoperative heparin is less likely to trigger acute platelet activation by the residual HIT antibodies.[111,112]

Patients with acute or recent HIT who require urgent heart surgery and still have detectable antibodies have been successfully treated with alternate anticoagulant approaches (e.g., bivalirudin, or heparin plus an antiplatelet agent such as epoprostenol or tirofiban), but each of these approaches has disadvantages. For example, epoprostenol causes hypotension, and there is limited experience with its use in cardiac surgery. Bivalirudin is a potential option for use in cardiac surgery, but special surgical and anesthesiologic maneuvers are required (because bivalirudin undergoes proteolysis, thus posing a risk for clotting of stagnant blood in the extracorporeal circuit). This author favors considering reexposure to heparin after HIT mitigating strategies (e.g., awaiting seroreversion, therapeutic plasma exchange, preoperative administration of high-dose IVIG, intraoperative administration of antiplatelet agents).[106,111,112]

A diagnostic and therapeutic approach to HIT is shown in the box on Diagnosis and Treatment of Heparin-Induced Thrombocytopenia.

DIAGNOSIS AND TREATMENT OF HEPARIN-INDUCED THROMBOCYTOPENIA

HIT should be clinically suspected when thrombocytopenia occurs during (or soon after) heparin therapy and the temporal profile of the decrease in platelet count is consistent with immune sensitization to heparin. Four relevant questions, the 4Ts, should be asked:

***T*hrombocytopenia:** Does the patient have thrombocytopenia? A greater than 50% fall in the platelet count can indicate HIT even if the platelet count has not fallen to below 150×10^9/L. (Note: Severe thrombocytopenia, such as a platelet count below 10×10^9/L, is only rarely caused by HIT.)

***T*iming:** Is the timing of the platelet count fall consistent with immune sensitization? In HIT the platelet count usually begins to fall 5–10 days after starting heparin (the first day of heparin is day 0); a more rapid fall in the platelet count can occur if the patient is already sensitized from heparin exposure within the past 100 days.

***T*hrombosis:** Does the patient have thrombosis or other sequelae of HIT? (Note: In addition to venous and arterial thrombosis, patients with HIT can develop necrotizing skin lesions at heparin injection sites or systemic inflammatory or cardiorespiratory reactions that begin 5–30 minutes after an IV heparin bolus.)

O*T*her: Are there other explanations for the thrombocytopenia? HIT is less likely when there is compelling clinical evidence for another cause of the thrombocytopenia, such as positive blood cultures or critical illness.

Steps in Management of Clinically Suspected Heparin-Induced Thrombocytopenia

1. Confirm that thrombocytopenia is present (repeat complete blood count), test for DIC, and test for HIT antibodies, preferably using a platelet activation test such as the SRA.
2. Assess clinically and radiologically for thrombosis (e.g., compression ultrasound for lower-limb deep venous thrombosis).
3. Stop all heparin, including heparin flushes.
4. Initiate treatment with an alternative anticoagulant, generally in therapeutic doses if HIT is strongly suspected (options: danaparoid[a,b] fondaparinux,[c] rivaroxaban,[c] apixaban,[c] argatroban,[c] bivalirudin[c]).
5. Although initial treatment decisions are made on clinical grounds, results of testing for HIT antibodies can influence subsequent treatment, including the decision to resume heparin if HIT has been ruled out. In some centers, the availability of rapid HIT assays allows for treatment decisions pending receipt of test results.

Caveats

- Do not use LMWH to treat HIT.
- Do not start (or continue) warfarin or other coumarins until the platelet count has returned to normal (>150×10^9/L), and give only in low initial doses (warfarin, 5 mg or less) and overlap with a parenteral anticoagulant for at least 5 days.
- Do give vitamin K (e.g., 5–10 mg IV over 30–60 min) if HIT is diagnosed after warfarin has already been given, so as to reduce the risk for coumarin necrosis and to avoid underdosing of DTI because of aPTT prolongation by warfarin.
- Beware of confounding[4,113] of aPTT-monitored DTI therapy in patients with severe HIT complicated by HIT-associated consumptive coagulopathy (DIC) or who have other explanations for an elevated aPTT, such as warfarin therapy, liver disease, or antiphospholipid syndrome.
- Do not give prophylactic platelet transfusions (platelet transfusions are appropriate if the patient is bleeding or if there is diagnostic uncertainty).
- Do not use inferior vena cava filters in patients with acute HIT; there is a high risk for progressive lower-limb venous thrombosis and even progression to venous limb gangrene, perhaps because anticoagulants used to treat HIT are not good at inhibiting surface-associated thrombin generation, and also because the presence of filter might discourage therapeutic-dose anticoagulation.

---

[a] Off-label treatment for HIT in the United States (although approved for the treatment of HIT in numerous other jurisdictions).

[b] Withdrawn from the US market but available in many other countries.

[c] Off-label treatment for HIT is listed as a treatment option in the American Society of Hematology (ASH) HIT treatment guidelines.[83]

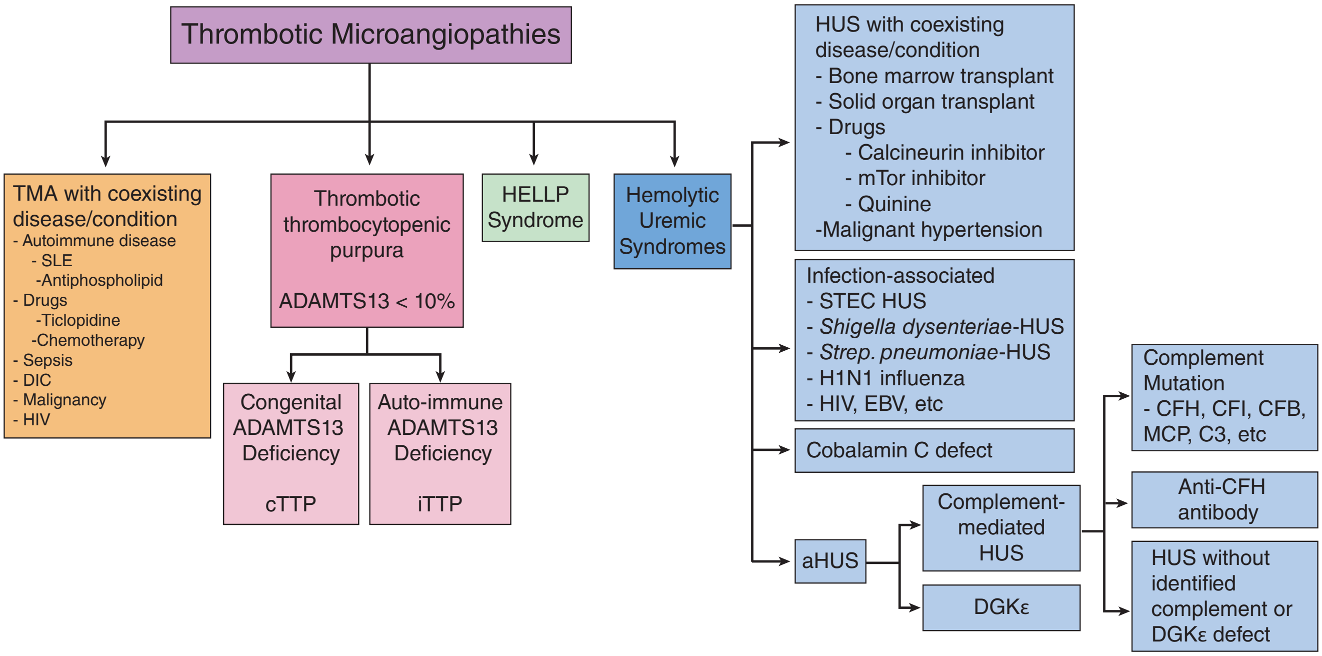
CHAPTER 132

THROMBOTIC THROMBOCYTOPENIC PURPURA AND THE HEMOLYTIC UREMIC SYNDROMES

Gemlyn George and Kenneth D. Friedman

In 1924, Moschowitz reported a case of a 16-year-old girl who died of a previously undescribed illness characterized by microangiopathic hemolytic anemia (MAHA), petechiae, hemiparesis, and fever.[1] Postmortem examination revealed numerous hyaline thrombi, most prevalent in the terminal arterioles and capillaries of the heart and kidneys. In 1936, four similar cases were reported by Baehr and colleagues, who proposed that the hyaline thrombi were secondary to agglutinated platelets. In 1947, Singer suggested that the term thrombotic thrombocytopenic purpura (TTP) be used to describe this disorder. In 1955, Gasser used the term hemolytic uremic syndrome (HUS) to describe a related syndrome consisting of Coombs-negative hemolytic anemia, thrombocytopenia, and renal failure. The physiology of these two disorders remained a mystery until 1982 when "unusually large" multimers of von Willebrand factor (VWF) were discovered in the plasma of patients with relapsing TTP.[2] The clinical features of Shiga toxin-associated HUS (ST-HUS) were described in five young children who presented with renal failure following a diarrheal illness in 1962.[3] An association between HUS and *Shigella* infections was recognized in 1975 and *E. coli* that produce Shiga toxin (Stx) were identified in 1983. These disorders are now collected under the rubric of *thrombotic microangiopathies (TMA)*, based on their shared features of MAHA, thrombocytopenia, and microvascular thrombotic lesions with resultant organ dysfunction.

MAHA and thrombocytopenia are cardinal signs/features of all TMA syndromes, leading to overlapping clinical and pathologic features. However, a multitude of different pathogenic pathways lead to vascular endothelial injury in these conditions (Fig. 132.1). Most cases of TTP appear to be due to deficiency of a disintegrin-like and metalloprotease with thrombospondin type1 motif, family member 13 (ADAMTS13) either through an autoantibody or a congenital deficiency. This deficiency results in failure to control the interaction of VWF with platelets and subsequent organ dysfunction is a consequence of platelet-rich thrombi formation in the microcirculation (and occasionally in large vessels). The TMA syndrome with MAHA, thrombocytopenia, and renal failure not associated with diarrhea or severe ADAMTS13 deficiency had been called "atypical" hemolytic uremic syndrome (aHUS). This is mainly attributable to a defect in the regulation of the complement mechanism and unregulated deposition of complement factor C3b on cellular surfaces and these are currently designated as complement-mediated HUS (CM-HUS). A rare autosomal recessively inherited form of TMA occurs in patients with defects in the gene encoding diacylglycerol kinase epsilon (DGKε), which results in a shift of endothelial cells to a prothrombotic phenotype. Similarly, mutations in the methylmalonic aciduria and homocystinuria type C (MMACHC) gene results in methylmalonic aciduria and homocystinuria progressing to TMA with renal failure.



Thrombotic Microangiopathies
TMA with coexisting disease/condition
- Autoimmune disease
- SLE
-Antiphospholipid
- Drugs
-Ticlopidine
-Chemotherapy
- Sepsis
- DIC
- Malignancy
- HIV
Thrombotic thrombocytopenic purpura
ADAMTS13 < 10%
Congenital ADAMTS13 Deficiency
cTTP
Auto-immune ADAMTS13 Deficiency
iTTP
HELLP Syndrome
Hemolytic Uremic Syndromes
HUS with coexisting disease/condition
- Bone marrow transplant
- Solid organ transplant
- Drugs
- Calcineurin inhibitor
- mTor inhibitor
- Quinine
-Malignant hypertension
Infection-associated
- STEC HUS
- Shigella dysenteriae-HUS
- Strep. pneumoniae-HUS
- H1N1 influenza
- HIV, EBV, etc
Cobalamin C defect
aHUS
Complement-mediated HUS
DGKε
Complement Mutation
- CFH, CFI, CFB, MCP, C3, etc
Anti-CFH antibody
HUS without identified complement or DGKε defect

Figure 132.1 CLASSIFICATION OF THE VARIOUS FORMS OF THROMBOTIC MICROANGIOPATHIES. *aHUS*, Atypical hemolytic uremic syndrome; *C3*, complement factor 3; *CFB*, complement factor B; *CFH*, complement factor H; *CFI*, complement factor I; *cTTP*, congenital thrombotic thrombocytopenic purpura; *DGKε*, diacylglycerol kinase ε; *DIC*, disseminated intravascular coagulation; *EBV*, Epstein-Barr virus; *HELLP*, hemolysis, elevated liver function tests, and low platelet count; *HIV*, human immunodeficiency virus; *iTTP*, immune thrombotic thrombocytopenic purpura; *MCP*, membrane cofactor protein; *SLE*, systemic lupus erythematosus; *STEC*, Shiga toxin-producing *E. coli*; *TMA*, Thrombotic microangiopathy. *(Adapted from Fakouri F, Zuber J, Frémeaux-Bacchi V, et al. Haemolytic uraemic syndrome. Lancet. 2017;390:681–696.)*

Finally, in hemolytic uremic syndrome due to Stx-producing *E. coli* (STEC-HUS), endothelial injury is caused by Stx and inflammatory cytokines, perhaps inciting disease with increased frequency in individuals with specific genetic predispositions. STEC-HUS is the main mechanism underlying infection-associated HUS (IA-HUS), but several other infections may lead to TMA through other mechanisms. With improved understanding of the pathogenesis of TMA and the availability of targeted therapies, distinction among the various TMA syndromes is important.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of MAHA and thrombocytopenia is extensive (Fig. 132.2). Vascular damage secondary to severe sepsis, autoimmune disorders (i.e., systemic lupus erythematosus, scleroderma, antiphospholipid syndrome), septic or tumor emboli, immune complex-mediated vasculitis (e.g., infective endocarditis), malignant hypertension, complications of pregnancy (severe pre-eclampsia, eclampsia, HELLP syndrome), cryoglobulinemia, infection with rickettsia, or, more rarely, hemorrhage-inducing viral organisms, may all lead to thrombotic microangiopathy. Occasionally, patients with disseminated intravascular coagulation secondary to malignancy or sepsis present with microangiopathy of sufficient severity to be confused with primary TMA (see Chapter 137). In the setting of renal transplantation, a biopsy may be required to distinguish TMA from allograft rejection or recurrence of a preexisting renal vascular disorder. Occasional patients present with acute pancreatitis, acute respiratory distress syndrome, memory and personality changes, or other poorly defined neurologic symptoms, which have a broad differential diagnosis.

There are clues that have suggested that STEC-HUS examination should include the patient's age at the time of presentation, ingestion of undercooked ground beef or other food that might have been contaminated by cattle, contact with farm animals, or concurrent clinical presentation by another family member. History of asynchronous presentation in a sibling suggests inherited TTP or CM-HUS. Historic approaches to distinguishing between TTP from CM-HUS relied on the age at presentation and the types of symptoms. However, as demonstrated by trials showing the utility of eculizumab, CM-HUS is not uncommonly diagnosed in adults. Similarly, there is significant end-organ dysfunction overlap between these two disorders. While the kidney remains a major target organ in CM-HUS, renal injury of sufficient severity to require dialysis may occur in up to 10% of patients with TTP. Neurologic symptoms are reported in 25% to 79% of patients diagnosed with TTP but may also be seen in 10% to 30% of patients with CM-HUS.

Choosing the appropriate therapy depends on an accurate diagnosis. Once MAHA and thrombocytopenia have been confirmed by examination of the peripheral smear, other systemic disorders (e.g., sepsis, progression of already established disease or complications of drug therapies) must be excluded. (See box on Management of Complement-Mediated Hemolytic Uremic Syndrome.)

The probability of TTP can be calculated using scoring systems (discussed below) in addition to ADAMTS13 activity testing. In the setting of rapidly progressing renal failure, complement-mediated TMA should be considered because early use of eculizumab has

been shown to prevent or reverse kidney injury. STEC infection should be ruled out as soon as possible if infection-ssociated HUS is considered, utilizing appropriate microbiologic studies (stool culture, immunoassay for Stx or fecal PCR). Children and young adults should be tested for a cobalamin C defect because defects in cobalamin metabolism may produce a similar hematologic picture (including thrombocytopenia, presence of bizarre microcytic red cells on the peripheral blood film, and elevations of lactate dehydrogenase [LDH] and bilirubin).

THROMBOTIC THROMBOCYTOPENIC PURPURA

Epidemiology

Acquired TTP or immune mediated (iTTP) accounts for 95% of all TTP cases and occurs with an estimated annual incidence of two to six cases per million (variation based on registry), but the incidence appears to be increasing, perhaps because of increased awareness. iTTP has a higher incidence in adults than in children and has a female/male ratio of 2–3:1 and a peak incidence in the fourth decade. Additional risk factors include blood group O, obesity, and African ancestry, which is also associated with an increased risk of relapse. Acquired TTP can occur in association with predisposing conditions such as autoimmune diseases, malignancy, infections, drugs, and pregnancy. TTP has been reported in approximately 0.3% of HIV-infected patients, usually in those with advanced disease.

Pregnancy is a common precipitating factor for both immune TTP (12% to 31% of individuals) and inherited severe ADAMTS13 deficiency.[4] Clinical symptomatic TTP most frequently develops in the second or third trimester, with the decrease in ADAMTS13 levels and increase in VWF and factor VIII that occur in normal pregnancy perhaps acting as precipitants.

Congenital TTP (cTTP), also known as Upshaw-Schülman syndrome, is less common than immune TTP. In general, most estimates of cTTP range from 0.5 to 2 cases per million. This incidence varies based on the region.

Pathobiology

TTP occurs when there is an inherited or acquired deficiency of ADAMTS13 (generally defined as less than 10%), leading to increased levels of "unusually large" VWF multimers that induce platelet aggregation in the microvasculature (Fig. 132.3).

TTP was first linked to VWF by Moake et al., who identified unusually large VWF multimers between disease flares in the plasma of patients with chronic relapsing TTP. He proposed that such patients lacked a plasma enzyme that cleaves these unusually large multimers and that accumulation of abnormally large multimers caused uncontrolled intravascular platelet aggregation, thrombosis, and tissue infarction. Subsequently, two separate investigators identified the plasma metalloprotease that degrades VWF multimers by cleaving the Tyr^{1605}-Met^{1606} bond in the VWF A2 domain (see Chapter 133). This metalloprotease is lacking in patients with TTP, including a subset with a presumably inherited form of TTP, and mixing studies demonstrated the presence of an immunoglobulin inhibitor in many of the non-inherited cases. It was also demonstrated that patients with clinically suspected HUS were not deficient in the metalloprotease, supplying the first clear evidence that the pathogenesis of TTP differs from that of HUS.

The breakthrough in the identification of the VWF cleaving protease happened in 2001 when genome-wide linkage analysis revealed that Upshaw-Schülman syndrome is caused by mutations in the ADAMTS13 gene on chromosome 9q34 (discussed within the inherited TTP section).[5] Almost simultaneously, three other groups working with the VWF-degrading protease (isolated from plasma or from commercial factor VIII/VWF concentrate) identified it as a member of the ADAMTS (A Disintegrin-like and Metalloprotease [reprolysin type] with ThromboSpondin type 1 motif) family of metalloproteases.; the designation 13 indicates that it was the 13th

Figure 132.3 PATHOPHYSIOLOGY OF THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP). In physiologic conditions, ultralarge von Willebrand factor (VWF) multimers released from endothelial cells are cleaved by ADAMTS13 into smaller VWF multimers, that are less adhesive to platelets. In TTP, because of absence of functional ADAMTS13 (either absent by congenital defect or inhibitor by specific autoantibodies), ultralarge VWF multimers are released into the blood and bind spontaneously to platelets to form aggregates within the arterial and capillary microvessels, The VWF-platelet aggregates are large enough to form microthrombi inducing tissue ischemia, platelet consumption and microangiopathic hemolytic anemia (schistocytes on blood smear). *(From Joly B, Coppo P, Veyradier A. Thrombotic thrombocytopenic purpura. Blood. 2017;129:2836–2846.)*

member of the ADAMTS family to be described. ADAMTS13 consists of multiple domains (Metalloprotease, Disintegrin-like domain, Thrombospondin type 1 repeat, Cysteine rich domain and Spacer domain, seven thrombospondin type 1 repeats, and two CUB [Complement components C1r and C1s, sea urchin protein Uegf, and Bone morphogenic protein-1] domains). The protein circulates in a folded conformation with the CUB domains interacting with the spacer domain. This folded structure suggests an autoinhibitory role in which the CUB domains shield exosites on ADAMTS13 to prevent unregulated enzyme activity and VWF proteolysis.

Endothelial cells secrete large VWF multimers that adhere to exposed collagen through their A3 domains. When VWF is tethered to collagen under high shear, these multimers elongate and reveal the platelet binding site for Gp1bα, which is in the A1 domain (see Chapter 123). This process facilitates platelet recruitment to the site of injury. While ADAMTS13 is generally maintained in a closed conformation with its CUB domains interacting and shielding the spacer domain, shear forces can open the conformation. Reciprocally induced conformational change in VWF and ADAMTS13 results in exposure of exosites on the enzyme and docking sites on VWF, culminating in regulated ADAMTS13-mediated cleavage of VWF in its A2 domain.[6] Such cleavage reduces the length of VWF multimers and curtails its capacity to form thrombi particularly in areas of high shear (e.g., small arterioles and capillaries).

The factors that trigger sporadic episodes of TTP by causing endothelial damage or activation remain undefined. Some patients with congenital deficiencies of ADAMTS13 may not develop TTP until adulthood, or not at all despite chronic ADAMTS13 deficiency. The latter observations suggest that ADAMTS13 deficiency should be considered an important predisposing factor, but not the sole cause of this syndrome. This concept is supported by studies of ADAMTS13-deficient mice, in which a TTP-like syndrome develops spontaneously in some genetic backgrounds (high VWF levels) but requires a triggering factor, such as Stx, in other strains.

Antibodies (abs) against ADAMTS13 work by inhibiting the proteolytic activity of ADAMTS13 on VWF or by increasing the clearance of ADAMTS13 from plasma by forming immune complexes. Most inhibitory immunoglobulins are directed against the spacer domain of ADAMTS13, but antibodies directed against carboxyl-terminal CUB1-2 and TSP2-8 domains also have been described. Confounding this finding were reports from serologic studies indicating that anti-ADAMTS13 IgG may be present in 5% of healthy individuals, 20% of patients with a TMA other than TTP, 13% of patients with SLE, and 5% of patients with antiphospholipid syndrome.[7] From a mechanistic standpoint, administration of the antibody alone resulted in a clinical syndrome resembling iTTP in baboon models.[8] Work from Roose et al., also suggests that the conformational state of ADAMTS13 is important in the pathogenesis of the disease.[9] Normally, ADAMTS13 is folded on itself in a "closed" and inactive conformation. However, ADAMTS13 opens when it docks with VWF. ADAMTS13 assumes an open conformation in the acute phase of the disease. This is important because, in the closed conformation, the spacer sites of ADAMTS13 are not accessible to autoantibodies. The factors that trigger the open conformation have yet to be discovered; however, one could hypothesize that there is a dynamic process, and that the presence of antibody stabilizes ADAMTS13 in the open conformation. From a clinical perspective, both high antibody levels and lower antigen levels are associated with mortality rates of 17% and 18%, respectively, while the combination appears to have a synergistic effect with a mortality rate of 27%.[10]

Many theories have been proposed to explain the onset of iTTP. The most prominent of these is the link between infections and iTTP. Proposed mechanisms include a two-hit model, cross reaction with $CD4^+$ T cells targeting microbiome derived peptides, variants in TLR-9 being more prone to producing Th1 cytokines and activation of the alternate complement pathway through interaction with unusually large VWF multimers.[11] Since the HLA system has been implicated in the development of autoimmune disease, research efforts have been directed to evaluation of the HLA system as a factor in the development of iTTP. The first association was reported in the 1990s with the antigens DR52 and DR53 from the HLA-DRB3 and HLA-DRB4 genes, respectively.[12] In 2010, two European studies demonstrated that HLA class 2 loci DRB1*11, DRB1*15, DQB1*03, and DQB1*06 were predisposing haplotypes for iTTP.[13] Interestingly, HLA-DRB1*04 and its associated HLA-DRB4-encoded serotype HLA-DR53 were shown to be protective against the development of iTTP. A Japanese group recently reported an association between HLA alleles DRB1*08:03, DRB3/4/5*blank, DQA1*01:03, and DQB1*06:01 and iTTP.[14] The increased incidence of iTTP in persons of African origin may reflect the low prevalence of the protective allele DRB1*04 in this ethnic group.[15]

Clinical Manifestations

The classic pentad of signs and symptoms of TTP syndrome include MAHA, thrombocytopenia, neurologic impairment, fever, and renal dysfunction. The complete pentad was most often described before the routine use of therapeutic plasma exchange. Earlier recognition of this syndrome and the established efficacy of plasma exchange, however, have led to the appreciation that MAHA and thrombocytopenia, in the absence of an obvious precipitating condition, are sufficient to make a presumptive diagnosis of TTP. In fact, at diagnosis less than 10% of patients present with the full pentad.

Approximately 10% to 40% of patients with TTP recall an upper respiratory tract infection or flu-like syndrome in the weeks preceding the diagnosis. Patients may present with malaise, fatigue, fever, or other nonspecific symptoms days to weeks in duration and are unresponsive to antibiotics or symptomatic management. The frequency of end-organ involvement is variable with the renal system, GI system, central nervous system, and cardiac system most often affected.

The central nervous system is the most often affected visceral organ at presentation with symptoms ranging from headache or transient confusion to severe symptoms such as seizures, TIA or stroke. Most patients have normal findings on imaging. Gastrointestinal symptoms occur in 35% to 40% of patients and include nausea, vomiting, abdominal pain or diarrhea. Acute renal failure requiring dialysis occurs in up to 5% to 15% of patients and severe renal dysfunction is more common in HUS. An elevated troponin may be identified in up to 70% of patients with TTP and is associated with worse prognosis.

Scoring systems incorporating clinical and laboratory parameters have been developed to enable prompt identification of patients with thrombotic microangiopathy who may benefit from plasma exchange (Table 132.1). These include the French score, the Bentley score and the PLASMIC score. The French score, which was derived from a cohort of 214 patients, has three components, (thrombocytopenia, creatinine level, and ANA) and has a negative predictive value of 93% with a score of zero.[16] The PLASMIC score contains seven components, and stratifies patients into low-, intermediate-, and high-risk categories.[17] It was developed to predict the likelihood of ADAMTS13 activity less than 10%. A high PLASMIC score (six to seven) is predictive of ADAMTS13 activity ≤10 with a sensitivity of 94%. Similarly, a low PLASMIC score predicts the absence of severe ADAMTS13 deficiency 98% of the time. A high probability score with either the French or the PLASMIC scoring system supports immediate initiation of plasma exchange.

Older adults (greater than 60 years) may have a distinct presentation compared with young adults. Atypical neurological symptoms such as confusion, headache, delirium, behavioral changes, TIAs, and stroke are commonly seen. Older patients present with greater renal impairment and less severe thrombocytopenia and anemia compared with younger patients. Consequently, the sensitivity of the PLASMIC score may be lower in older individuals, which can lead to a delay in diagnosis. Critically, the scoring systems developed for use in TTP were validated with populations containing an over representation of younger patients. In a study by the French group for TMA, only 61% of older patients with severe ADAMTS13 deficiency were as high risk using the French score.[18]

Laboratory Manifestations

The presence of schistocytes on the peripheral blood smear is a characteristic laboratory finding of TTP (Fig. 132.4). In most TMAs, schistocytes account for more than 1% of all erythrocytes. A finding of two or more schistocytes per high-power field is suggestive of MAHA. However, there is no threshold number below which the possibility of TTP can be excluded. More subtle signs of RBC fragmentation may be seen early in the course of the disease. Thrombocytopenia in TTP reflects deposition of platelets in microthrombi. In a series of 70 patients with TTP, the mean platelet count on presentation was 10,000.

TABLE 132.1 **PLASMIC and French Score Prediction of Likelihood of Severe ADAMTS13 Deficiency of Thrombotic Thrombocytopenic Purpura in Cases of Suspected Thrombotic Thrombocytopenic Purpura**

Parameter	French Score	PLASMIC Score
Platelet count	<30,000/μL: +1	<30,000/μL: +1
Serum creatinine level	<2.26 mg/dL: +1	<2.0 mg/dL: +1
Markers of hemolysis • Indirect bilirubin >2 mg/dL • Undetectable haptoglobin • Reticulocyte count >2.5%	[a]	+1
No active cancer in previous year	[a]	+1
No history of solid organ or stem cell transplant	[a]	+1
International normalized ratio (INR) < 1.5	[a]	+1
Mean corpuscular volume (MCV) < 90 fL	—	+1
Likelihood of severe ADAMTS13 deficiency (< 10%)	**Score = 0: 2%** **Score = 1: 70%** **Score = 2: 94%**	**Score = 0–4: 0%–4%** **Score = 5: 9%–24%** **Score = 6–7: 62%–82%**

[a] French score assumes microvascular hemolysis (schistocytes present) and absence of clinical evidence for associated cancer, transplantation or disseminated intravascular coagulation, and did not incorporate mean red cell volume.

TTP, Thrombotic thrombocytopenic purpura.

Derivation and external validation of the PLASMIC score for rapid assessment of adults with thrombotic microangiopathies: a cohort study. *Lancet Haematol*. 2017;4(4):e157-e164; and Zheng XL, Vesely SK, Cataland SR, et al. ISTH guidelines for the diagnosis of thrombotic thrombocytopenic purpura. *J Thromb Haemost*. 2020;18:2486–2495.

ADAMTS13 activity testing is critical for the diagnosis of TTP. However, therapy should not be delayed while waiting for results of this test if the clinical suspicion for TTP is high. An activity level of less than 10% confirms the diagnosis of TTP in patients with MAHA and thrombocytopenia without any other obvious cause. ADAMTS13 activity less than 10% has been noted in rare cases of sepsis and systemic cancer and thus cannot be used exclusively as a diagnostic test; the clinical context must also be considered.

ADAMTS13 activity assays involve incubation of plasma with substrate full-length VWF multimers or truncated peptides containing the ADAMTS13 cleavage site. The substrate undergoes proteolysis by ADAMTS13 in the test plasma and enzyme activity is measured by detecting the cleavage product or by measuring the residual VWF. The first generation of assays used VWF as the substrate with urea or guanidine hydrochloride to expose the cleavage site in the VWF A2 domain. Current methods for ADAMTS13 level measurement utilize VWF peptides that undergo rapid cleavage when exposed to ADAMTS13, with endpoints based upon detection of fluorescence due to separation of emitter and quencher adducts that become separated through the cleavage process (fluorescence resonance energy transfer [FRET]–based assays utilize substrates such as VWF-VWF73 peptide), immunologic detection of the cleaved end of a solid-phase adherent residual peptide or a surface-enhanced laser desorption/ionization time-of-flight mass spectrometry. The antigen assays quantify the ADAMTS13 protein levels in plasma which includes both free active enzyme as well as inactive ADAMTS13 in complex with autoantibody.

The measurement of ADAMTS13 inhibitor levels using a functional inhibitor assay and/or autoantibody assay should also be performed when possible because the results are useful for predicting the clinical course and for distinguishing between iTTP and cTTP (see discussion in pathophysiology). Functional inhibitor assay is performed by mixing patient plasma with a source of ADAMTS13 (such as normal pooled plasma) and measuring the residual ADAMTS13 content. Inhibitor units are reported in a fashion analogous to how Bethesda units are quantified in the setting of hemophilia; one inhibitor unit is defined as the amount of inhibitor that will neutralize 50% of the ADAMTS13 activity when mixed into an equal volume of normal pooled plasma. Neutralizing antibodies interfere with ADAMTS13 proteolytic activity whereas non-neutralizing antibodies promote ADAMTS13 clearance from plasma. Several factors can

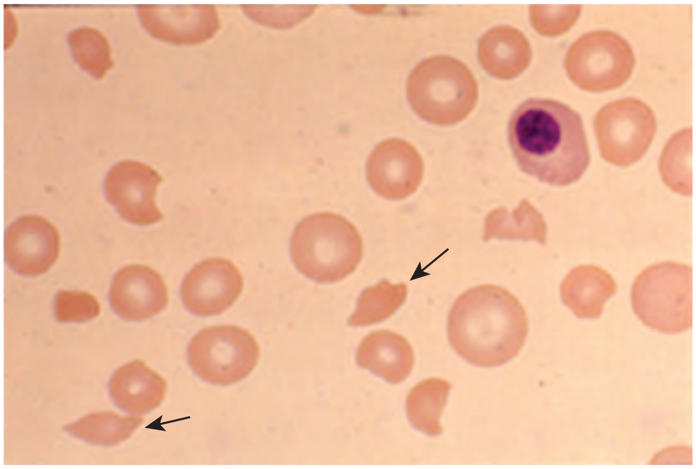

Figure 132.4 PERIPHERAL BLOOD FILM OBTAINED FROM A 28-YEAR-OLD WOMAN WHO PRESENTED WITH FEVER, EPISTAXIS, AND ALTERED MENTAL STATUS. Note the absence of platelets and the presence of a nucleated erythrocyte and schistocytes *(arrows)*, consistent with a microangiopathic process.

affect the detected ADAMTS13 activity and inhibitor. Samples for testing cannot be collected in EDTA because it chelates the metal ions required for ADAMTS13 activity. Other interfering substances include hyperbilirubinemia and severe lipemia, which interfere with the FRET-based assay. Antibody assays quantify anti-ADAMTS13 antibody levels (usually IgG but may also be IgM and IgA) using ELISA, western blotting, or immunoprecipitation. ADAMTS13 inhibitor assays identify and quantify anti-ADAMTS13 antibodies that functionally inhibit ADAMTS13 in vitro. If severe ADAMTS13 deficiency persists and inhibitor or antibody assays are negative, a diagnosis of cTTP should be considered and ADAMTS13 sequencing should be performed.

Inherited ADAMTS13 Deficiency (cTTP)

TTP was initially considered an acquired disorder, with the term TTP suggested in 1947 (after the discovery of systemic microvascular thrombosis) to distinguish this disorder from immune thrombocytopenic purpura (ITP). The hereditary occurrence of TTP was first described in 1975 by Wallace et al., who noted an autosomal recessive inheritance pattern.[19] A series of reports, including one by Upshaw, reporting improvement in clinical outcomes with plasma infusion resulted in the eponymous name. Subsequently, genome-wide linkage analysis revealed that Upshaw-Schülman syndrome is caused by mutations in the ADAMTS13 gene on chromosome 9q34.

ADAMTS13 is mainly synthesized by hepatic stellate cells but also by vascular endothelial cells and renal glomerular podocytes. Small amounts of functional ADAMTS13 are present in platelets. More than 200 mutations that can cause inherited TTP have been reported, and they involve almost all structural domains of ADAMTS13. Most of these mutations are single amino acid missense substitutions and most patients are carriers of compound heterozygous mutations. Mutations affecting the highly conserved N-terminal domains of ADAMTS13 are associated with lower residual enzyme activity, more severe clinical phenotype, and probably presentation of disease earlier in life. Expression studies have shown that missense mutations usually prevent the secretion of ADAMTS13, although some also impair catalytic activity. Specific mutations have been noted in population clusters with studies in Norway identifying the mutation p.R1060W and the insertion c.4143_4144dupA in approximately 0.3% to 1% of the population.[20] Similarly, other clusters have been noted in regions around the Baltic Sea, central Europe, Japan, and in Scandinavia. Because some of these mutations are associated with residual ADAMTS13 activity, the disease is often identified during pregnancy with patients sometimes presenting with severe pre-eclampsia. However, residual activity is not the only determinant of age at first disease manifestation.

Patients with cTTP are at risk for manifestation at any time in life. In general, however, the risk is highest at birth and with pregnancy. A 2011 study describing the natural history of cTTP in Japan identified 43 cases in patients ranging in age from childhood to 79 years.[21] Of these cases, 42% were diagnosed during childhood, 36% between the ages of 15 and 45 (all female, most commonly presenting during pregnancy), and 12% beyond 45 years of age. Likewise, a registry from the United Kingdom also reported a large variation in age at symptom onset ranging from childhood to adulthood.[22]

Newborns with TTP may present with hyperbilirubinemia, anemia, and severe thrombocytopenia. The pathophysiology of the presentation is due to an abrupt increase in systemic vascular resistance after circulation to the placenta stops in the setting of a high hematocrit and ultra large VWF multimers. Plasma infusion is the treatment of choice in this setting. Children who survive often remain asymptomatic for years.

In the Japanese cohort of 43 patients, 9 of 20 women were diagnosed with TTP during pregnancy. Antecedent pregnancies were associated with severe complications. cTTP should be considered in women presenting with pre-eclampsia at less than 25 weeks of gestation. Patients with cTTP have a high risk of stroke and TIA. In a cohort of 73 patients in the United Kingdom, 19% of patients had a stroke and another 8% a TIA.[23] The reported median age at presentation was 19 years; however, cases have been reported in patients over 60 years of age. Strokes can occur in the absence of hemolysis or thrombocytopenia. It has been estimated that 25% of strokes may be embolic with an undetermined source (see Chapter 144).[24] Interestingly, rates of myocardial infarction are much lower compared with that of stroke.[25] Acute kidney injury and chronic kidney disease have also been reported in patients with cTTP. As men do not experience the stress of pregnancy, recurrent stroke in males of young age should raise the possibility of hereditary TTP.

The absence of a functional ADAMTS13 inhibitor or antibody is characteristic of cTTP. False positive results with FRET-based functional assays can occur with severe hemolysis and a high hemoglobin concentration. The diagnosis of cTTP is further suspected if ADAMTS13 deficiency persists when the patient is in clinical remission and is confirmed by genetic analysis. As noted earlier, CNS symptoms may occur without thrombocytopenia or evidence of hemolysis; patients may also present with AKI. Fortunately, from a therapeutic perspective, plasma therapy results in rapid clinical recovery. In pregnant women with cTTP, monitoring of blood counts and prophylactic administration of plasma decrease the incidence of pregnancy complications and fetal loss, fostering a safer antenatal course.

The half-life of ADAMTS13 activity in patients receiving prophylactic plasma infusions is 2.5 to 3.5 days. Treatment intervals between plasma infusions have been empirically determined and depend on clinical symptoms and maintaining a normal platelet count. As a result, there is a wide variation in the recommended treatment intervals between infusions. Plasma derived factor VIII/VWF concentrates containing ADAMTS13 (Koate DVI and BPL 8Y) have been used for the treatment and prophylaxis of hereditary TTP. As a cautionary note, inhibitory alloantibodies can develop in patients receiving plasma therapy. In a phase 1 study, recombinant, fully glycosylated ADAMTS13 expressed in Chinese hamster ovarian cells (BAX 930; SHP 655; rADAMTS-13) was safe and well tolerated.[26] This product is under investigation in a multicenter study with results expected in 2023.

Multiple questions remain in the field of cTTP. From an epidemiological perspective, additional studies with case finding strategies need to be performed. In addition, strategies to optimize replacement therapy protocols using plasma derived or recombinant ADAMTS13 are required to avoid complications of pregnancy, preserve renal function and prevent large vessel occlusive disease (stroke and myocardial infarction).

TREATMENT OF THROMBOTIC THROMBOCYTOPENIC PURPURA

The goal of treatment in TTP is to prevent microvascular obstruction and replenish ADAMTS13 levels. Depending on the underlying etiology of ADAMTS13 deficiency—inherited or acquired (autoimmune)–replacement or replacement with immunosuppression +/− interruption of thrombus formation forms the thrust of therapy. The clinical presentation of TTP can be dramatic. When hemolysis and thrombocytopenia raise the specter of TTP, the PLASMIC score is useful to make a presumptive diagnosis and guide therapy. The reason for haste is the high mortality rate, which in the absence of therapy can exceed 90%, and the fact that the clinical situation can rapidly deteriorate.

The initial approach to TTP through the mid-70s focused on splenectomy, antiplatelet agents, high doses of glucocorticoids and whole blood exchange transfusions. The proposed rationale for exchange transfusion was to remove “a toxic substance.” Byrnes and Khurana established that plasma provides the critical factor for the treatment of TTP, ushering in a naive era in its treatment. (See box on Management of Acute Thrombotic Thrombocytopenic Purpura.)

MANAGEMENT OF ACUTE THROMBOTIC THROMBOCYTOPENIC PURPURA

- A high index of suspicion is necessary to make a diagnosis of thrombotic thrombocytopenic purpura (TTP)
  - Evaluate pretest probability of TTP based upon clinical assessment and risk assessment tool (PLASMIC or French Score)
  - Send ADAMTS13 assays (activity and either inhibitor or IgG antibody) before initiating therapy if such testing is available. In an appropriate clinical setting, an ADAMTS13 activity result <10% confirms a diagnosis of TTP
  - If pre-test probability is high, begin therapy for TTP. If pretest probability is intermediate or low, initiation of treatment of TTP is based upon clinical judgement while awaiting ADAMTS13 studies.
- Initial treatment of an acute episode of TTP:
  - Start plasma-based therapy. Plasma exchange (1.0–1.5 plasma volume) is recommended. Plasma infusion may be considered until exchange can be initiated, or potentially in a patient with known congenital TTP (cTTP)
  - In a patient with suspected or confirmed iTTP, begin corticosteroid therapy.
  - Anti-VWF therapy with caplacizumab is guided by ADAMTS13 activity assay results. Consider anti-VWF therapy with caplacizumab before ADAMTS13 results return if results are pending and patient has a high pretest probability, or after ADAMTS13 activity result returns at <10% for patients with low or intermediate pretest probability (use clinical judgement for activity result 10%–20%).
  - Consider early immunotherapy (e.g., rituximab) if iTTP is confirmed with ADAMTS13 inhibitor or anti-ADAMTS13 IgG assay, or if such diagnosis is highly suspected.
  - Platelet transfusion should be reserved for life-threatening bleeding. Packed red cell transfusion can be safely transfused in TTP.
- Subsequent treatment of an acute episode of TTP:
  - Continue plasma-based therapy until patient achieve clinical remission based on clinical symptoms, lactate dehydrogenase, and platelet count.
  - In treatment responders:
    - Continue anti-VWF therapy with caplacizumab for 30-day course or based upon ADAMTS13 activity results.
    - In patients with iTTP, complete immunotherapy treatment course.
  - In treatment non-responders, consider investigation for confounding conditions (such as infection). Alternative/additional therapies should also be considered.
- Subsequent follow-up:
  - For patients with iTTP, continued monitoring of ADAMTS13 activity is suggested as pre-emptive immunotherapy retreatment has been shown to decrease incidence of clinical disease relapse.
  - For patients with cTTP, ADAMTS13 replacement therapy (with plasma) prevents relapses and improves outcomes of pregnancy. Indications for chronic or episodic prophylactic replacement therapy remain to be defined, and clinical judgement is required.

Initial Treatment

Plasma Exchange in Thrombotic Thrombocytopenic Purpura

With the use of plasma infusion and plasma exchange, the survival of patients with TTP has increased to over 80% to 90%. The overarching debate in the late 70s and early 80s was the effectiveness of plasma infusion versus plasma exchange. In a nationwide trial conducted in Canada over a 7-year period, investigators addressed this question by randomizing patients to treatment with aspirin and dipyridamole and either plasma exchange or plasma infusion with fresh frozen plasma (FFP).[27] At 6 months, complete remissions were seen in 78% of patients treated with exchange versus 31% of those treated with plasma infusion. This study confirmed the superiority of plasma exchange over plasma infusion likely reflecting the fact that plasma exchange results in both the removal of the IgG inhibitor of ADAMTS13 and replacement of the deficient protein. In contrast, plasma infusion (or infusion of ADAMTS13 concentrate) suffices for patients with congenital ADAMTS13 deficiency. Large volumes of plasma are more easily administered by exchange, and unless a genetic deficiency of ADAMTS13 has been documented, plasma infusion should be reserved for situations in which exchange is not immediately available. The recovery of ADAMTS13 levels may lag behind other indicators of clinical response, and the utility of monitoring ADAMTS13 levels during acute treatment has not been established (see below concerning anti-VWF therapy with caplacizumab).

Plasma (either FFP or thawed plasma) is used for plasma exchange. There is no clear advantage for the use of cryo-poor plasma (CPP), which is depleted of VWF. These findings are consistent with a study showing similar concentrations and stability of ADAMTS13 during storage at 1°C to 5°C in CPP and FFP. Pilot studies suggest that solvent-detergent treated plasma (SDP), which contains ADAMTS13 at concentrations approximately 20% lower than those in FFP is as efficacious as FFP and is associated with fewer allergic/urticarial reactions. In the UK, SDP is used for all patients with TTP.[28]

Treatment is generally initiated with the goal of exchanging 1 to 1.5 plasma volumes (40 to 60 mL/kg) daily, although the optimal regimen has not been determined. Some experts advocate increased volumes of exchange if the initial response is poor. Neurologic improvement occurs most rapidly, often within hours to days. The serum LDH level typically falls by 50% within 3 days in responders, and the platelet count begins to rise at a mean of 5 days, though normalization may take several weeks. Improvement in renal function and disappearance of schistocytes occur more slowly.

Daily plasma exchange should be continued until neurologic symptoms have resolved and both a normal serum LDH and platelet count have been achieved; many experts recommend an additional 2 to 3 days of plasma exchange thereafter. Approximately 85% to 90% of patients exhibit a clinical and laboratory response to plasma exchange within 3 weeks, most often within 10 days (mean: 16 days; range: 3 to 36 days). However, 20% to 40% of patients will experience an exacerbation of disease within 30 days after stopping plasma exchange, whereas approximately 30% will relapse at later dates, usually within the first year. Limited data are available to support the decision between abrupt discontinuation or “tapering” of plasma exchange after remission.

Complication rates associated with plasma exchange therapy have been reported to be as high as 30%, but recent reports suggest a lower rate. Most adverse events are related to central venous catheter insertion, infection, allergic reactions to plasma, and occasionally thrombosis.

Plasma exchange is effective for patients with or without demonstrated inhibitors, and clinical responses frequently occur despite persistence of both the inhibitor and severe ADAMTS13 deficiency, although patients with high titer inhibitors may respond more slowly and relapse more often. Both congenital and acquired ADAMTS13 deficiency is characterized by unpredictable periods of stability between relapses, probably reflecting exacerbation of the disease by co-morbid conditions that activate or damage the endothelium, thereby increasing the release of unusually large VWF multimers, and triggering microvascular thrombosis.

Immunosuppression

Immunosuppression with glucocorticoids and anti-CD20 monoclonal antibody (rituximab) are a cornerstone of therapy in patients with iTTP. Glucocorticoids aid recovery by reducing production of autoantibodies to ADAMTS13. Therapy is typically started with oral prednisone at a dose of 1 to 2 mg/kg/day; a higher dose of methylprednisolone (1000 mg daily) may be used for critical illness. Prednisone was compared to cyclosporine in a randomized control trial and was found to be more effective in increasing ADAMTS13 activity and suppressing antibodies (study stopped after an interim analysis).

Anti-CD20 therapy with rituximab has been shown to reduce the risk of exacerbations and relapse and to hasten the response to therapy. Consequently rituximab is often given before plasma exchange is completed. Rituximab should ideally be given after plasma exchange to minimize its removal by the procedure, but its use should not delay plasma exchange. Rituximab has been shown to effectively deplete $CD20^+$ lymphocytes within 24 hours of infusion even with ongoing plasma exchange therapy.

The data supporting the utility of rituximab come mainly from observational studies. The STAR trial evaluated the benefit of adding rituximab to plasma exchange and glucocorticoids as initial treatment. Unfortunately, the trial was stopped because of poor accrual.[29] Data from a phase 2 study suggested that rituximab was safe and effective when given within 3 days of an acute TTP admission.[30] Compared with historical controls, inpatient stay was reduced by 7 days, and 10% of patients given rituximab relapsed compared with 57% in the historical control population. The dose of intravenous rituximab used for acquired TTP has generally followed the traditional schedule of 375 mg/m² once weekly for 4 consecutive weeks. A prospective multicenter single arm phase 2 trial using a fixed dose of 100 mg weekly for four doses showed response rates similar to those achieved with the higher dose.[31] Another approach pioneered by the French Thrombotic Microangiopathy group has been to use an adaptive dose of rituximab in response to B cell depletion.[23] Rituximab use in the acute phase of TTP prompts a high response rate (greater than 90% in the first month) and extends the time to relapse. The median time to relapse across studies conducted in the United Kingdom and France and using data from the Oklahoma TTP registry indicate a median time to relapse between 24 and 29 months.

Anti–von Willebrand Factor Therapy (Caplacizumab)

Microvascular thrombosis, the hallmark of TTP, occurs because of unregulated interaction of ultra-large VWF with platelets. Interruption of that process with anti-VWF therapy has the potential to halt microvascular obstructions and organ ischemia. Caplacizumab is a humanized, bivalent, variable domain only immunoglobulin fragment that targets the A1 domain of VWF and blocks its interaction with platelet glycoprotein lb-IX-V. In the randomized controlled phase 3 HERCULES trial, 145 patients with acquired TTP were randomly assigned to receive caplacizumab or placebo daily until 30 days after the last daily plasma exchange (plasma exchange was performed daily until at least 2 days after normalization of the platelet count).[32] All patients received daily plasma exchange and glucocorticoids and could receive other immunosuppressive therapies (slightly less than half received rituximab). Caplacizumab was associated with faster normalization of the platelet count, fewer days of plasma exchange, fewer exacerbations in the 30 days after stopping plasma exchange (4% vs. 38%) and a shorter course of hospitalization (10 vs. 14 days). Caplacizumab was associated with more bleeding (65% vs. 48%) which resolved spontaneously. In addition, a composite outcome of TTP related death, recurrence of TTP or a major thromboembolic event occurred in 12% of patients in the caplacizumab group and in 49% of those in the placebo group. Normalization of markers of organ dysfunction occurred sooner with caplacizumab than with placebo. The findings of more rapid platelet count response, reduced organ damage and conservation of resources, prompted the recent ISTH guidelines to suggest that caplacizumab be initiated in all patients with a high probability of having TTP in whom confirmation via ADAMTS13 assay is anticipated.[33] Based upon the initial phase 2 Titan and the phase 3 Hercules trial experience, it is recommended that caplacizumab be continued for 30 days after discontinuation of plasma exchange. Relapses were noted in patients who had severely suppressed ADAMTS13 activity below 10% at the end of the 30-day period after the last plasma exchange. As supported by the HERCULES trial data, some groups recommend monitoring ADAMTS13 activity level at that point and continuing caplacizumab therapy until ADAMTS13 levels recover to above 20% to prevent exacerbations of disease. Successful treatment of TTP with caplacizumab without concomitant plasma therapy has been reported in several individual cases and a recent case series.[34] Situations prompting this approach have included patients with contraindications to plasma therapy (such as history of severe allergic reactions to plasma or inadequate venous access) and patient refusal of plasma therapy (including religious objection to blood products). Because plasma exchange is the standard of care for TTP and use of caplacizumab alone is off-label, the decision to omit plasma-based therapy must be shared between the patients and their physicians. Trials of caplacizumab alone are needed in patients with TTP.

Other Modalities

Before the introduction of plasma therapy, splenectomy was the first-line treatment for TTP and induced remission in up to 50% of patients. Currently, splenectomy is reserved for patients who are refractory to all other modes of treatment. Antiplatelet agents have fallen out of favor and are now part of the historical construct of TTP treatment. Similarly, immunosuppressive agents like cyclophosphamide and vincristine are no longer used now that rituximab is available. Other adjunctive therapies that have fallen out of favor include azathioprine, mycophenolate mofetil, staphylococcal protein A immunoadsorption, and bortezomib. However, these may still be considered in refractory cases or in patients with iTTP whose ADAMTS13 levels fail to rise with rituximab.

Historically, platelet transfusions have not been recommended for patients with TTP because of their potential to provoke fatal thrombotic events. Data from the Oklahoma TTP-HUS registry challenged this dogma.[35] In a cohort of 54 consecutive TTP patients (of whom 47 had ADAMTS13 activity less than 10%), 33 patients received platelet transfusions. There was no difference in the incidence of death or severe neurologic events. The authors of the study concluded that there was “uncertain evidence of harm” with platelet transfusion in TTP. Although platelet transfusion might be considered prior to vascular access device placement, catheters for apheresis can safely be inserted even in the face of severe thrombocytopenia (less than 10,000). Therefore, based on accumulating evidence, platelet transfusion in TTP patients should be reserved for those with life-threatening bleeding.

Subsequent Therapy and Monitoring Response

Once a patient with TTP is stabilized, subsequent treatment is dictated by close monitoring for disease relapse and by immunosuppression. Disease response to therapy can be assessed using the platelet count. A good response is a platelet count over 150,000/μL for at least 3 days or a stable plateau. In addition to the platelet count, weekly monitoring of the LDH and ADAMTS13 level is suggested but well-established protocols do not exist. Schistocytes may persist for some time after the thrombocytopenia has resolved. Ultimately, normalization of the platelet count and improvement in symptoms are the most reliable indicators of response to therapy, while an increase in ADAMTS13 levels indicates a biochemical response.

Plasma exchange can be stopped once the platelet count is over 150,000 for at least 2 days. Plasma exchange may be stopped abruptly or may be tapered off, but the tapering is not of proven benefit. In the first month after discharge from the hospital, patients with TTP should have frequent blood counts and monitoring for symptoms (e.g., starting three times weekly and gradually tapering to once a week by the end of the first month if there has been no relapse). A relapse is generally preceded by a drop in the platelet counts below 100,000/μL. More frequent monitoring of symptoms and blood counts should be considered if the platelet count falls below 150,000. If the platelet count falls below 100,000 and ADAMTS13 activity is low or symptoms suggestive of a relapse (e.g., neurologic symptoms) develop, plasma therapy and/or further treatment with immunosuppression or anti-VWF therapy is indicated. If there is no relapse in the first month, glucocorticoids are generally tapered over 2 to 3 weeks while the rituximab course is completed. ADAMTS13 levels should be measured periodically after stopping plasma exchange until levels normalize. Patients with intermediate ADAMTS13 levels (20%—the lower limit of normal) may merit more frequent monitoring. Patients are at an increased risk for relapse in the first year with illness or surgery serving as potential triggers. ADAMTS13 levels should be checked every 3 months for the first year with more frequent if the level falls below 40%.

The use of immunotherapy and anti-VWF therapy (caplacizumab and rituximab) reduces the risk of exacerbations and relapses. Rituximab has decreased the frequency of relapse to about 13% with most relapses occurring over a year after plasma exchange is discontinued. The use of preemptive rituximab is supported by the results of a study from the French TMA group[36]; 48 of 233 patients had an ADAMTS13 level less than 10% and 30 were treated with rituximab preemptively. Whereas the 18 patients not treated preemptively had a median relapse free survival of 9 years, patients given rituximab did not reach a median relapse-free survival. This report was followed by a second study demonstrating a decrease of relapse from 74% with a median follow-up of 7 years versus 15% with a follow-up of approximately 3 years.

Therapy for patients with a history of iTTP whose ADAMTS13 level fall over time remains uncertain. Some experts suggest a single dose of rituximab followed by re-evaluation of the ADAMTS13 level in a month and withholding further therapy if the level is greater than 40% and giving additional weekly doses if the level remain less than 40%. Other experts suggest "maintenance" doses of rituximab, including the use of lower doses. The UK TTP registry demonstrated equivalence among 3 dose levels (375 mg/m^2 once per week for 4 weeks, 200 mg once per week for 4 weeks, 500 mg once per week for 4 weeks) with no differences in time for the recovery of ADAMTS13 levels and need for retreatment. If the patient has had multiple relapses with no effect of maintenance rituximab on ADAMTS13 levels, other immunosuppressive agents or splenectomy could be considered.

Patients with acquired TTP that does not respond to initial treatment with plasma exchange and immunosuppression within 4 days or with ongoing disease activity, as evidenced by thrombocytopenia or neurological symptoms, are considered refractory. In these patients, therapy may be intensified using a higher dose of glucocorticoids (1 g IV of methylprednisolone daily for 3 days) and addition of caplacizumab and rituximab (if not given already). Alternate diagnoses that could contributing to the refractory state need to be considered. These include infection, occult malignancy, or medications. With refractory disease, cyclophosphamide, bortezomib, cyclosporine, mycophenolate may be considered.

Patients with iTTP are susceptible to subsequent relapses and must be educated about the need to seek immediate medical care should symptoms arise. They also are at higher risk for hypertension, major depressive disorders, autoimmune diseases (SLE), and stroke compared with age and sex matched controls.

Special Scenarios

In patients with religious considerations that preclude them from accepting blood products, caplacizumab has been used successfully. Factor VIII concentrates that contain ADAMTS13 have been used in cTTP. Plasmapheresis with albumin as replacement fluid may be considered to reduce the ADAMTS13 autoantibody while waiting for immunosuppression effect to take hold. For patients presenting with TTP during pregnancy, retrospective data suggest that plasma exchange is the initial treatment of choice. These pregnancies are at a higher risk for intrauterine fetal demise due to thrombosis of the decidual arterioles.

INFECTION-ASSOCIATED HEMOLYTIC UREMIC SYNDROME

Clinical Manifestations

Infection-associated Stx-STEC-HUS is one of the main causes of acute renal failure in children.[37] Patients generally present with the triad of hemolytic anemia, thrombocytopenia, and acute kidney injury. STEC-HUS occurs most commonly after *E. coli* O157:H7–induced gastroenteritis, with rare cases reported after infection of the urinary tract or skin, or after infection with organisms other than *E. coli*. Based on data from O157:H7 outbreaks in which the time of exposure can be determined, the sudden onset of abdominal pain and watery diarrhea begins on average 4 days (range: 2 to 12 days) after toxin exposure.[38] Abdominal pain may be severe and precede the onset of diarrhea. In the absence of fever, STEC-HUS may be difficult to differentiate from inflammatory bowel disease, appendicitis, ischemic colitis, or intussusception. Bloody diarrhea generally ensues on the second day, accompanied in some cases by nausea and vomiting, though up to one-third of patients do not report blood in the stool. Fever is typically absent or mild. Colonoscopy reveals edematous colonic mucosa with occasional ulceration and pseudomembrane formation.

E. coli–associated hemorrhagic gastroenteritis is complicated by HUS in 8% to 18% of sporadic cases, and in over 20% in certain epidemic outbreaks. Therefore, the disease should be suspected in a patient who presents with characteristic clinical manifestations after an episode of bloody diarrhea, although the prototypic history of a preceding hemorrhagic gastroenteritis may be absent in up to 30% of cases. Young children and older adults are at greatest risk. When bloody diarrhea first develops, the platelet count, creatinine, and hematocrit are typically normal. However, as infection progresses, platelet counts often fall. HUS typically develops 7 days (range, 5 to 13 days) after the onset of diarrhea.[39,40] Patients often present with oliguria or other evidence of renal impairment; 50% to 75% of patients require dialysis, at least temporarily. The severity of MAHA varies considerably, but many affected individuals require red cell transfusion. Thrombocytopenia is common, with a median platelet count of 30,000/μL in one study but may be mild or absent in up to 30% of cases at presentation. Up to 25% of patients develop neurologic manifestations, which may include irritability and somnolence and less commonly, confusion, paresis, and seizures. The mortality rate is estimated at 3% to 5%.

Epidemiology

STEC-HUS accounts for at least 90% of cases of infection associated HUS.[41] In one study conducted in the United States, the median age of patients with STEC-HUS was 4 years; 55% of patients were younger than 5 years of age, 33% between 5 and 17 years, 6% between 18 and 44 years, and 6% older than 45 years of age. The annual incidence of STEC-HUS is estimated to be 2 to 3 per 10^5 in children under age 5. Shiga toxin-producing *E. coli* (STEC) accounts for 80% to 86% of cases in the United States and Europe. The most common serotype of *E. coli* associated with HUS is O157:H7, although other serotypes including O26:H11, O103:H2, O111:NM, O21:H19, O145:NM, and O104:H4 have been reported. The major reservoir of STEC is domestic cattle; approximately 2% to 3% harbor STEC in their gastrointestinal tract at the time of slaughter, and meat can become contaminated during processing. The organism has also been isolated from deer, sheep, goats, horses, dogs, birds, and flies. Large outbreaks have been reported in association with ingestion of contaminated ground beef, although contamination of poultry, cheese, fruits, and vegetables has also been reported. Other cases have been attributed to ingestion of contaminated water or unpasteurized apple cider or milk. The incidence of STEC-HUS may be increasing because of changes in food production methods. Industrial farming generates large quantities of potentially contaminated manure that periodically enters streams, where it can contaminate feed and uncooked vegetables. A 2011 outbreak of HUS in Northern Germany that affected more than 3000 individuals was caused by enteroaggressive *E. coli* O104:H4; the infection vector was traced to bean sprouts with evidence of intra-household transmission.[42] Similarly, in 2018, an outbreak related to contaminated romaine lettuce affected 135 people, resulting in 85 hospitalizations and 15 cases of HUS. Carriage of STEC may be asymptomatic, and fecal-oral transmission may contribute to epidemic spread in day care centers, nursing homes, and petting zoos. Aerosolization in barns has been implicated in outbreaks at fairs.

STEC strains are also associated with sporadic, nonepidemic cases of HUS. The disease occurs more frequently during the summer and autumn in temperate climates. Infection by Stx-producing *Shigella dysenteriae* serotype 1 is associated with HUS in developing countries and carries a higher mortality.

Pathobiology

STEC-HUS is caused by endothelial cell damage initiated by Stxs and the inflammatory cytokines they induce. The type of Stx, as well as other virulence factors, contribute to risk.

After ingestion, the noninvasive enteropathic *E. coli* colonize the terminal ileum and follicle-associated epithelium of Peyer patches, after which they colonize the colon. Once colonization occurs, STEC bacteria express numerous virulence factors by horizontally transmitted gene cassettes termed pathogenicity islands. One pathogenicity island contains the locus of enterocyte effacement (LEE), which contains genes for the adhesin intimin, as well as a type III secretion system (TTSS) that mediates transfer of bacterial proteins directly into enterocytes. Their capacity to cause HUS is mediated by two 70-kD bacterial exotoxins. The toxins are transported across the intestinal epithelium through specific para- and intercellular mechanisms and then circulate, most likely by low affinity binding to the surface of neutrophils and platelets, before being transferred to higher affinity receptors expressed on glomerular endothelial cells that are upregulated by proinflammatory cytokines.

The toxin produced by these strains of *E. coli* is identical to Shigella toxin and is therefore generally referred to as *Shiga-like toxin 1 (Stx1)*. Most strains of pathogenic *E. coli* produce a second homologous toxin, Stx2, which is associated with a higher risk for HUS. The toxins are carried on a lysogenic bacteriophage capable of infecting other strains of *E. coli*. Intact, 70-kD Stx holotoxins consist of a 32-kD A subunit responsible for inactivating ribosomal activity, and five 7.7-kD B receptor-binding subunits that aid in binding to the target receptor. The toxin binds to terminal Gala1-4Galb (galabiose) residues on globosyltriaosylceramide (Gb_3; also known as *CD77* and the human blood group *P^k antigen*). Increased expression of Gb_3 on glomerular microvascular and cerebral endothelium compared with other vascular beds contributes to their heightened sensitivity to apoptosis, cytotoxicity, upregulation of integrins, and procoagulant activity. The higher levels of Gb_3 expression in children compared with adults may explain why children are particularly prone to develop HUS.

After binding to Gb_3, Stx1, and Stx2 are internalized and transported in a retrograde manner to the endoplasmic reticulum and translocated into the cytosol. The A subunit is proteolyzed to a 27-kD A1 subunit that binds the 60 S ribosomal subunit and cleaves adenine 4323 from the 28 S ribosomal RNA. This prevents elongation factor 1-dependent binding of aminoacyl tRNA, which inhibits protein synthesis and leads to ribotoxic stress response, changes in cellular function, and apoptosis. Stx alters the usual balance between intestinal absorption and secretion to a net excretory phenotype. *E. coli* lipopolysaccharide and Stx also stimulate leukocyte and intrarenal expression of proinflammatory cytokines (including IL-1, IL-1β, IL-6, and IL-8; MCP-1; and interferon-γ), which exacerbate toxin- and leukocyte-induced endothelial dysfunction. Changes in endothelial function include upregulation of expression of Stx receptors, which further sensitizes cells to Stx-induced injury, increased expression of P-selectin and tissue factor, increased release of VWF, and down-regulation of thrombomodulin expression. Early in the course of the disease, Stx also acts in concert with lipopolysaccharide to trigger a procoagulant state that involves platelet activation.

It remains unclear why a minority of patients infected with STEC bacteria develop STEC-HUS.[43] Activation of complement may contribute to the pathogenesis of Stx-HUS. Stx2 directly activates the alternative pathway of complement and binds to SCR 6 to 8 and 19 and 20 of complement factor H (CFH), which mediate surface recognition of complement C3, blocking the ability of factor H to inhibit complement activation on cell surfaces. It has been hypothesized that subtle allotypic variation in CFH may modulate the sensitivity of CFH to Stx2-induced dysregulation in susceptible patients.[43]

Laboratory Manifestations

Similar to TTP, STEC-HUS is characterized by MAHA and thrombocytopenia. Thrombocytopenia tends to be less severe than observed that in TTP, and renal disease is the major clinical manifestation.

Renal biopsy, although rarely required for diagnosis in endemic areas, illustrates the importance of endothelial damage. Involved glomeruli show widening of the subendothelial space, which is filled with cellular debris and fibrin. Glomerular capillary endothelial cells are swollen and occasionally detached, leading to obliteration of the capillary lumens.

Though clinical features are often sufficient for the diagnosis of STEC-HUS, bacteriologic confirmation should be sought through stool culture, testing for Stx toxin (e.g., by ELISA), stool analysis for Stx structural genes, or acute and convalescent serologies. Stool should be tested as soon as possible after the onset of diarrhea. Because of the importance of expedited diagnosis, obtaining a rectal swab is suggested over waiting for a cup stool specimen. In a study of children with diarrhea, rectal swabs had a higher pathogen yield than cup stool specimens.[44] The recovery rate for STEC appears to be at least 90% during the first 6 days but less than 33% thereafter. *E. coli* O157:H7 ferments sorbitol slowly, appearing as colorless overnight colonies on sorbitol-MacConkey agar; sorbitol-negative cultures may be further characterized using commercially available O157:H7-specific antisera. Methods to detect Stx toxins or their structural genes improve diagnostic sensitivity. However, enzyme immunoassay (EIA) may fail to detect 10% to 15% of *E. coli* O157:H7 that are detected through culture[45]; thus, EIA is used in addition rather than instead of culture. Molecular panels that detect the genes for Stx 1 and 2 can deliver a result within several hours and can distinguish between these two toxins as well as other enteric pathogens.[46] If the lab report does not specify which Stx genes are present, it is critical to request that information, as the presence of Stx 2 represents a much higher risk of HUS than if this toxin is not present.

Antibody titers against *E. coli* O157:H7 antigens and Stx rise after infection, persist for 8 to 12 weeks, and may be useful to confirm STEC infection in selected cases; however, they are not widely available. In some cases, further evaluation may be desired to differentiate STEC-HUS from the other TMA, such as autoimmune disease, aHUS and TTP.

Imaging studies, such as computed tomography are rarely indicated in children suspected of STEC; however in adults in whom immunologic intestinal disorders may present as bloody diarrhea, CT imaging may be of value.

Prognosis

The outcome of patients with STEC-HUS is generally favorable, although STEC-HUS remains the most common cause of acute renal failure in children and up to 60% of children require dialysis during the acute phase. However, STEC-HUS is usually self-limited and as a result of advances in supportive care, mortality has been reduced to 3% to 5%, with death usually due to severe involvement of the central nervous system, intestine, or myocardium. Renal insufficiency generally resolves within 2 to 3 weeks, although some patients have prolonged anuria, requiring several months before recovery. Despite a favorable short-term outcome, many children with STEC-HUS develop chronic renal insufficiency over time. In one report of 29 patients with "typical" childhood HUS followed for 15 to 28 years, seven developed chronic renal failure and 12 developed hypertension, proteinuria, or reduced glomerular filtration rate, whereas only 10 showed no residual abnormalities. Therefore, 50% to 60% of patients have complete recovery with long-term preservation of renal function. Long-term outcomes are worse in older patients. Proteinuria persisting for more than 1 year after the initial episode of TMA is likewise associated with progressive renal disease.

Therapy

Treatment of STEC-HUS is supportive.[47] Because high risk of STEC causes severe illness, patients presenting with acute bloody diarrhea require careful evaluation, particularly if they present with absence of fever. Observation over a course of at least 6 hours is suggested to determine if symptoms of pain or diarrhea are abating, to suggest a more benign situation. If STEC is suspected, supportive therapy is important to initiate early.[48] Volume expansion within the first 4 days of the onset of diarrhea is performed to maintain renal perfusion as it significantly reduces the incidence of progression to oliguric HUS. Early and aggressive volume expansion with isotonic crystalloid is suggested. The volume administered is adjusted based upon age of the patient and in adults, by whether there are cardiopulmonary morbidities. However, no therapy has been shown to prevent HUS or to reduce the severity of kidney injury once established. In randomized trials, neither plasma infusion nor exchange was of benefit in children or adults with STEC-HUS. Corticosteroids, heparin, urokinase, aspirin, dipyridamole, antifibrinolytic drugs, and intravenous immunoglobulin are ineffective. Antimotility agents and narcotics delay clearance of *E. coli* and toxin from the GI tract and may increase the risk for progression to thrombotic microangiopathy; therefore, these agents should be avoided. Nonsteroidal anti-inflammatory agents may reduce renal blood flow and should also be avoided. Most experts believe that antibiotics increase the risk for progression to HUS, probably by lysing bacteria, releasing Stx and inducing bacteriophages on which Stx genes are expressed. This conclusion is supported by a large meta-analysis that included mostly observations studies in children, showing a trend towards higher risk of HUS with antibiotic use.[49] Therefore, routine use of antibiotic is discouraged.

Activation of complement may contribute to the pathogenesis of STEC-HUS. Increased levels of markers of alternative pathway activation and C5 convertase, as well as soluble C5b-C9 have been observed in patients with STEC-HUS. An uncontrolled retrospective study of 33 children with severe complications of STEC suggested a potential benefit in patients with severe neurologic complications. However, anticomplement therapy with anti-C5 monoclonal antibody eculizumab did not appear to improve 1-year renal outcome in that single center matched cohort study. Similarly, during the 2011 German O105H4 STEC-HUS epidemic, eculizumab was administered most commonly to patients with the most severe organ compromise and those often late in the course of disease. The outcome in these patients was similar to that in untreated patients.[50] Finally, during that German outbreak, immunoadsorption was undertaken in a small cohort of patients with severe neurologic compromise; while clinical benefit was reported, most of these patients also received other therapeutic interventions.[51] Additional data on the utility of eculizumab and immunoadsorption are needed before their routine use can be recommended.

Isolation of patients with STEC-HUS should be considered because shedding of the pathogenic bacteria may continue long after cessation of diarrhea.

ATYPICAL HEMOLYTIC UREMIC SYNDROME

Epidemiology

HUS is defined by MAHA and kidney injury is generally the predominant clinical feature. Broadly, this can be subdivided into infection associated HUS or complement-mediated HUS. Historically, children with HUS without diarrhea were described as having "atypical" HUS to make a distinction from HUS with a diarrheal prodrome caused by enteric infection. As a result, the term atypical HUS is composed of clinical HUS with dysregulation of the alternative complement pathway (CM HUS), mutations in the DGKε (diacylglycerol kinase ε) pathway (not thought to directly affect complement pathway regulation) and HUS without identified complement or DGKε mutation or anti-CFH antibody (see Fig. 132.2).

In children with HUS, the proportion with STEC-HUS is 85% to 90% while atypical HUS is 5% to 10%. The frequency of atypical HUS is not precisely documented in adults as the diagnosis in adults can be challenging and adults can present with any of the TMA syndromes associated with acute kidney injury-both genetic and acquired.

Abnormalities in complement regulation, most commonly due to mutations in complement regulatory proteins have been implicated in up to 50% of cases.[52] Inheritance is autosomal dominant with an estimated penetrance of 50%. aHUS can occur in siblings with or without identical genetic abnormalities. Clinical conditions that increase complement activation may unmask the genetic propensity to develop aHUS. The incidence of aHUS in the United States has been estimated at two per million based on the incidence of diarrhea negative HUS including *S pneumoniae* HUS, whereas European data suggest an annual incidence of 0.23 to 0.42 cases per million.[53]

Pathophysiology

The complement system is part of the innate immune system, enhancing the ability of antibodies and phagocytic cells clear microbes and damaged cells. It consists of multiple proteins synthesized by the liver, circulating in the blood as inactive precursors.

The complement system monitors the environment, protecting the intravascular space against bacterial invasion. The initial deposition of C3b can be mediated by the classical pathway by immune complexes, by the lectin pathways via interaction of bacterial carbohydrates with lectin-binding proteins, or via spontaneous hydrolysis of C3 to C3a and C3b (Fig. 132.5). C3b formation is then amplified by a positive feedback loop of the alternative pathway. C3b is deposited on almost all biological surfaces in contact with plasma resulting in its deposition on both pathogen surfaces as well as upon healthy host cells. This process wherein a small amount of autoactivated C3 is always present is called C3 tick-over. On healthy human cells, this process is terminated by control proteins (such as complement factors H, I, and CD46). However, on foreign or damaged cells, the alternative pathway is engaged when this activated C3 binds factor B. Bound factor B undergoes proteolytic cleavage by factor D to produce fragments Bb and Ba. This is further stabilized by properdin (p), creating a convertase complex C3bBbP. This "C3 convertase" cleaves more C3 to C3b setting an amplification loop in motion.

C3b binds to the C3 convertase to form C3bBbC3b which is the "C5 convertase." Like the stabilization process with C3 convertase, properdin also becomes part of C5 convertase, stabilizing the enzyme. C5 convertase goes on to cleave more C5 releasing C5a which acts as an anaphylatoxin while C5b initiates formation of the lytic membrane attack complex, built thought the cooperative actions of C6, C7, and C8 and resulting in polymerization of a pore through the cell membrane composed of multiple units of C9.[54]

To protect host cells from "collateral damage" as a consequence of complement C3b deposition, the process of complement activation on healthy cells is regulated through control proteins anchored onto membranes and in the fluid phase. The most prominent regulators of

Figure 132.5 CONSEQUENCES OF COMPLEMENT ACTIVATION. (A) The complement system can be activated via three pathways: classical, lectin, and alternative. All pathways lead to formation of powerful enzymes, the C3-convertases, followed by activation of the terminal cascade. The main effector functions of complement (promotion of opsonophagocytosis by opsonization and chemotaxis and formation of lytic membrane attack complexes) aim to destroy harmful agents such as microbes. Lysis of target cells can lead to damage-induced enhancement of complement activation. (B) Alternative pathway activation is based on continuous, low-level covalent deposition of C3b molecules onto practically all surfaces in contact with plasma. If the C3b molecule is allowed to form an enzyme (shown in red), new C3b deposits will be formed around the enzyme leading to rapid amplification of the activation. If the regulator factor H binds to C3b, the convertase enzyme is inactivated, and no complement activation follows. The simultaneous interaction of factor H with both C3b and cell surface sialic acids (or possibly glycosaminoglycans [GAGs]) is essential for proper regulation on self-red cells, platelets, and endothelial cells. If this fails, disbalance between activation and regulation may lead to pathogenesis of atypical HUS. iC3b, C3b molecule incapable of forming an enzyme with factor B. *(From Jokiranta TS. HUS and atypical HUS. Blood. 2017;129(21):2847–2856.)*

the alternate pathway are complement factor I (CFI), CFH which are plasma based proteins along with CD35, CD46, CD55, and CD59 which are membrane proteins. CFI is synthesized in the liver and functions by cleaving C3b to inactive C3b and dissociating the C3 and C5 convertases. Foreign targets that do not have membrane-bound regulators or cannot bind soluble regulators are attacked. Similarly, CFH inhibits the alternate pathway by binding to C3b, both when deposited on cells and in the fluid phase, through competition with factor B for C3b binding. Factor H also acts as a cofactor for CFI. CD46, previously known as membrane cofactor protein (MCP), is a widely expressed transmembrane regulator that serves as a cofactor for CFI. Intact MCP is critical in preventing C3 activation on glomerular endothelium. In addition to the above, variants for genes involved in the coagulation pathway including thrombomodulin, vitronectin (*VTN*), and plasminogen have been reported in patients with aHUS; however, the pathogenic contribution of these protein remains to be confirmed.

Mutations in these inhibitory proteins (CFI, CHH, and CD46) or gain of function mutations in C3 or complement factor B (CFB) or autoantibodies to alternate pathway proteins (usually anti-CFH) provide a “first hit” which puts the individual at risk. Subsequently, a “second hit” through an inflammatory process propagates complement activation which then creates a vicious cycle leading to endothelial injury and a prothrombotic state.[55]

Genetics

Earlier reports suggested that genetic mutations account for at least 50% to 60% of aHUS or CM-HUS (Table 132.2). Of these, the most common belong to CFH with 20% to 30 % of all cases (40% to 45% in familial cases and 10% to 20% in sporadic form).[52] Clinically, the appearance of the syndrome is sporadic despite the presence of pathogenic variants in the patient and one of the parents suggesting incomplete penetrance. Up to 3% of patients have combined pathogenic variants of more than one complement protein, potentially increasing the risk of disease. However, many of the mutations reported were published before more rigorous criteria from the American College of Molecular Genetics were established, and the pathogenicity of reported sequence variants remains to be substantiated though either larger family or population studies, or through demonstration of functional defects through expression experiments.

More than 193 potentially pathogenic variants have been identified in the *CFH* gene (as indicated by the FH aHUS mutation database). The majority of *CFH* mutations in patients with aHUS are heterozygous and cluster in the C-terminal, of the protein, and the region responsible for CFH binding to the cell surface glycosaminoglycan.[56] As a result, there is a lower density of CFH on cell surfaces and diminished cofactor activity for degradation of C3b that has become adherent to the cell surface. Most abnormal CFH forms are secreted in plasma; it is hypothesized that mutant CFH interacts with normal CFH and inhibits its binding to endothelial cells resulting in a dominant negative effect. Thus, even though individuals with heterozygous mutations may have normal circulating CFH antigen, they are predisposed to development of the aHUS phenotype. As most patients are heterozygous for the mutation, serum CFH and C3 levels are often normal. In patients with the homozygous *CFH* mutation, they may have a quantitative CFH deficiency, failure to control C3, and very low C3 levels. In a French cohort of patients with aHUS, patients with *CFH* mutations had the worst clinical outcome with a significantly worse renal prognosis when compared to other subgroups.[53] In addition to mutations in genes encoding *CFH*, factor H autoantibodies have been described in 10% of patients, these patients more often had them since childhood.[57] These antibodies have been shown to block the C-terminal recognition domain of factor H—the same region in which functionally significant mutations are present. Adjacent to the gene encoding for CHF are a series of genes encoding for a series of homologous proteins, CFHR1, CFHR2, CFHR3, CFHR4, and CFHR5. Homozygous deletion of gene encoding factor H–related protein 1 (*CFHR1*) either through homozygous or compound heterozygous deletion of region encoding for *CFHR3-CFHR1* or *CFHR1-CFHR4* were noted in these patients, suggesting that congenital absence of CFHR1 protein predisposes to risk for development of autoantibody to CFH with development of aHUS.

TABLE 132.2 **Complement Genes and Proteins Identified in Atypical Hemolytic Uremic Syndrome**

Mutated Gene	Mechanism of Disease	Prevalence (%)	ESRD/Death 3–10 Years After Onset (%)
CFH	Loss of complement regulation	24–28	70–80
CFHR1/3 deletion with anti-factor H antibodies	Loss of complement regulation	3–10	30–70

[a] MCP mutations are frequently found in combination with other mutations (up to 22%).

CFHR, Complement factor H-related gene; *DGKε*, diacylglycerol kinase epsilon gene; *ESRD*, end-stage renal disease; *MCP*, membrane cofactor protein gene; *THBD*, thrombomodulin gene.

Prevalence and prognosis data relates to publications before the introduction of eculizumab, have been adapted from multiple authors, including Noris M, Fremeaux-Bacchi V, and Bresin E. Adapted from Jokiranta TS. HUS and atypical HUS. *Blood.* 2017;129(21):2847–2856.

Mutations in CD46 or MCP account for 5% to 15% of HUS cases.[58] These patients tend to do well if they present in childhood. Adults however have a significantly higher rate of end-stage renal disease (ESRD). Patients who undergo a renal transplant for this condition have a low rate of recurrence in the allograft, a finding attributed to the fact that CD46 is a cell surface protein which is expressed on the surface of the normal renal allograft cells. Mutations in factor I are mostly heterozygous and occur in 4% to 10% of cases. These patients have an intermediate prognosis with 50% progressing to ESRD or death in 2 years.[59] Complement factor 3 mutations account for 2% to 10% of cases and present with severe disease. "Gain of function" in C3 variants is attributed to failure of variant C3b to be effectively regulated by CFH, CD46 and CFI. *CFB* mutations are gain of function mutations and are seen in 1% to 4% of all cases. *CFB* mutations lead to enhanced formation or greater stability in C3 convertase on cell surfaces.[52]

Mutations in *DGKε* which encodes DGKε were described in children with disease onset before 12 months of age.[60] DGKε is a lipid kinase, present on endothelial cells, podocytes, and platelets, that catalyzes the phosphorylation of diacylglycerol substrates to phosphatidic acid. Loss of DGKε function results in enhanced activation of protein kinase C which in turn results in the upregulation of prothrombotic factors (VWF, tissue factor and plasminogen activator inhibitor). As *DGKε* sits outside the complement pathway, there is no pathogenic rational to suspect that complement directed therapy would be effective in affected patients. However, some reports have shown remission if there are coexisting mutations with genes from the complement pathway.

Vitronectin is a protein present in serum and in the extracellular matrix that is involved in complement activation, coagulation, cell adhesion, and wound healing. It inhibits the terminal complement cascade by blocking the formation of the membrane attack complex. Mutations in the gene encoding for vitronectin (*VTN*) have been recently implicated in aHUS.[61]

Clinical Manifestations

The clinical symptoms of HUS are non-specific and includes fatigue, low urine output, edema, and dyspnea. Though aHUS is generally not associated with a prodrome of bloody diarrhea, a history of recent gastroenteritis may be obtained from up to 30% of patients, making distinction from STEC HUS difficult. A triggering event may be seen in roughly 30% of adults and half of children. The hallmark of the disease is the classic triad of thrombocytopenia, hemolytic anemia, and acute kidney injury. Correspondingly, evidence of microangiopathy on the peripheral blood film is a universal finding with an elevated reticulocyte count and LDH. Renal damage can be present with nephrotic range proteinuria with up to 75% of adult patients requiring dialysis.[53,62] Some patients can also develop accelerated hypertension, complicating the initial diagnosis. It has been suggested that in the absence of another cause for a renal thrombotic microangiopathy (such as STEC-HUS, systemic lupus erythematosus, scleroderma, medication effect, complications of transplantation), the presence of a creatinine over 2.3 mg/dL and a platelet count over 30,000/μL argues against a diagnosis of TTP and favors aHUS. However, cohort studies in patients with TTP indicated that some patients did require dialysis; suggesting that these disorders may be indistinguishable on clinical grounds alone, thereby highlighting the importance of ADAMTS13 assessment. Extra renal manifestations are present in 8% to 25% of patients at presentation, and can include neurological symptoms (~10%), GI involvement (~5%), cardiac involvement[63] (10% as myocardial infarction or ischemic cardiomyopathy) or ulcerative-necrotic skin lesions.

Typically, aHUS follows a chronic relapsing course, often complicated by hypertension and renal insufficiency. Moreover, exacerbations are often preceded by infection, pregnancy, or other seemingly incidental events. Affected patients have a high risk for recurrence after renal allografting, and HUS occasionally presents in related renal allograft donors after surgery. The disorder may resemble TMA associated with pregnancy, cancer, and chemotherapy, which have similar clinical presentations, but different natural histories.

Laboratory Testing

aHUS is characterized by MAHA and thrombocytopenia. Compared with TTP, thrombocytopenia and anemia may be less severe and renal insufficiency more prominent. Reports suggest that between 6% and 15% of children do not have the full triad of thrombocytopenia, anemia, and renal dysfunction at presentation.

Diagnosis of aHUS requires several criteria, including: (1) the absence of other diseases associated with TMA, (2) the absence of criteria for pathogen-associated post-infectious HUS (i.e., negative stool culture and/or Stx assays), and (3) the absence of criteria for TTP (i.e., ADAMTS13 greater than 10%, no anti-ADAMTS13 antibodies). Recommended studies include obtaining levels of C3, C4, CFH, and CFI, flow cytometry studies for CD46, and serologic studies for anti-CFH antibodies before initiating plasma exchange therapy. However, it is important to note that decreased C3 is only found in 30% to 40% of patients and that decreased CFH or CFI antigen is only seen in 50% or 30% of patients with mutations in these genes respectively, and between 30% and 60% of patients with auto-antibodies to CFH.[53] Also, decreased levels of C3 and decreased MCP expression may be observed in the acute phase of STEC-HUS. Due to variable penetrance, only 20% to 30% of patients will have a family history of aHUS. Screening for mutations *in CFH, CFI, MCP, C3, CFB, THBD*, and recombination events involving CFH related genes (CFHR1-5) complete the diagnostic work up. Recently, two research teams have suggested that assays with cell-based endpoints have the potential to be informative in the diagnosis and management of patients with aHUS due to defects on complement regulation. One group has proposed an assay utilizing a recombinant cell line in which the PIG-a gene has been modified, resulting in failure of the cells to link control proteins CD55 and CD59 to the cell surface, rendering the cells susceptible to complement-mediated killing when exposed to the plasma of patients with defects in the alternative pathway of complement activation.[64] The second assay utilized cultures of microvascular endothelial cells that are activated with ADP and then exposed to patient plasma. Deposition of C5b9 complex is then assessed by confocal microscopy.[65] Such assays may hold promise for confirming failure of complement regulation to help affirm a diagnosis of aHUS, allow evaluation of the efficacy of anticomplement therapy, assessment of the risk for discontinuation of anticomplement therapy in an aHUS patient who has been stabilized with anticomplement therapy, and potentially identify other disease states in which failure to control complement is considered a potential pathogenic mechanism. Two diseases in that last category that are being studies are pre-eclampsia and catastrophic antiphospholipid syndrome (see Chapters 139 and 149). While cell-based assays hold promise, even if proven sensitive and specific, there remain multiple hurdles in making such assays generally available for patient diagnosis and management. As a result, these assays have not yet been universally adopted in diagnostic testing.

Prognosis

Atypical HUS has been historically associated with a poor prognosis, especially in older adults and those with severe renal dysfunction. The historic mortality rate approaches 25% and 50%, with many surviving patients developing chronic renal insufficiency. However, identification of the central role of control of complement and DGKε in the pathogenesis of aHUS allows prognostication based on genotype. Before the advent of specific anticomplement therapy, the prognosis of patients with genetic defects of factor H or factor I deficiency was poor, with a rate of recurrence and progression to ESRD or death of 70%, whereas MCP deficiency appeared to carry a better prognosis, with estimated progression to ESRD between 15% and 20%.[41] Aggressive plasma-based treatment is associated with improved hematologic parameters and may slow but does not prevent progression to renal failure. Anticomplement treatment with eculizumab (and the second-generation longer half-life ravulizumab), a humanized monoclonal antibody directed at complement factor C5, has been shown to halt disease activity and improve renal function. In fact, some participants in the single armed trials were able to discontinue dialysis therapy. Eculizumab is ineffective in patients with disease due to DGKε mutations unless there are coexisting mutations in the

MANAGEMENT OF COMPLEMENT-MEDIATED HEMOLYTIC UREMIC SYNDROME

- A high index of suspicion is necessary to make a diagnosis of complement-mediated hemolytic uremic syndrome (CM-HUS)
    - CM-HUS is a systemic disorder
        - Advanced renal failure, hypertension and increased vascular permeability suggest a diagnosis of CM-HUS rather than thrombotic thrombocytopenic purpura (TTP).
        - Neurologic and gastrointestinal symptoms are common.
- CM-HUS is a diagnosis of exclusion:
    - TTP should be excluded by ADAMTS13 assay
    - IA-HUS should be excluded with stool culture and/or tests for Shiga toxin.
    - Other causes of microangiopathic hemolytic anemia should be excluded with history, coagulation studies, infectious disease studies, serologies, etc.
    - Plasma studies of C3, C4, and complement proteins (CFH, CHI, CFB) and autoantibody to CFH may be normal, as may genetic studies (CFH, CFI, CFB, C3, MCP, THBD, and DGKε). Initiation of therapy should not be delayed while awaiting these study results.
- Treatment of suspected acute CM-HUS:
    - Plasma exchange is recommended until a diagnosis of TTP is excluded.
    - Anti-complement therapy (such as eculizumab or ravulizumab) is currently the therapy of choice for CM-HUS.
        - Vaccination to prevent meningococcal infection is required; antibiotic coverage should be initiated pending immunization effect and chronic antibiotic prophylaxis should be considered.
        - Early treatment reduced the risk of long-term renal impairment.
        - Thrombocytopenia and hemolysis tend to respond early, but renal recovery may be delayed.
- Subsequent follow-up:
    - Long-term anticomplement therapy is currently recommended. If anti-complement therapy is discontinued, close follow-up to detect early relapse with re-initiation of therapy (and potential prophylaxis during high-risk intervals) is suggested.

CFB, Complement factor B; *CFH*, complement factor H; *CFI*, complement factor I; *DGKε*, diacylglycerol kinase epsilon; *IA-HUS*, infection-associated HUS; *MCP*, membrane cofactor protein.

complement pathway. As might be expected with an intracellular protein deficiency, no recurrences have been observed in the few reported DGKε cases where renal transplantation was performed.

Therapy

Historically, patients presenting with TMA (either TTP or aHUS) were offered a trial of plasma exchange therapy. Plasma exchange may still be indicated in patients where there is uncertainty about the diagnosis of TTP or aHUS pending the results of assays for ADAMTS13, or until more definitive anticomplement therapy is available. This approach is also being questioned in patients presenting with platelet counts over 30,000/μL and creatinine levels over 2.3 mg/dL, findings that are observed more often in association with aHUS than with TTP. Although plasma therapy replaces missing soluble regulators of the alternative mechanism of activation of complement and may ameliorate thrombocytopenia, it does not appear to halt renal disease progression, as evidenced by a high incidence of ESRD in pediatric patients treated with this approach. Plasma-based therapy is at best temporizing and is associated with a high rate of complications.

Eculizumab is a recombinant humanized monoclonal immunoglobulin that binds C5 with high affinity and inhibits its cleavage to C5a (a proinflammatory mediator) and C5b (the first component of the C5b-9 membrane attack complex). In this way, it interrupts the pathway leading to endothelial cell damage, but it does not interrupt the activation of C3 as shown by sensitive biomarker studies. It has been studied in four prospective trials (one in children, three in adults).[66,67] Identification of complement gene mutations were not required in these studies. However, they did assess the ADAMTS13 to screen out patients with thrombotic microangiopathy due to TTP. Eculizumab did ameliorate disease activity in the majority of treated patients, whether or not they were refractory to plasma therapy. Several patients with severe renal insufficiency were able to discontinue dialysis. The increase in GFR was more pronounced in children compared to adults, with early drug initiation more likely to be associated with recovery of renal function.

Anticomplement therapy is the treatment of choice for patients with established aHUS or with a high clinical likelihood in an appropriate setting (e.g., postpartum status, positive family history, younger than 2 years of age). Patients with markers of active TMA (thrombocytopenia, LDH, and haptoglobin) respond rapidly to therapy. The results of trials and accumulating registry data suggest that the sooner treatment is initiated, the better the chance of recovery of renal function. Current data also suggest that remissions are sustained. While on therapy, complement activity through CH50 should be monitored (less than 10% for complete suppression).

Anticomplement therapy is associated with meningococcal infections with an annual rate of 0.5%.[68] Patients should be vaccinated for *Neisseria meningitis* and potentially for *S. pneumoniae* and *Haemophilus influenza* type b. Cases of meningococcal disease have been identified in eculizumab recipients despite vaccination. As a result, prophylaxis with antibiotics during the treatment period is not unreasonable.

Discontinuation of anticomplement therapy can be attempted in patients who have had an excellent response to therapy.[69] However, this requires close follow-up with initially weekly blood work and twice weekly urinalysis, with early re-introduction of therapy if markers indicate disease reactivation. An increased sC5b-9 plasma level at eculizumab discontinuation, female gender and the presence of a rare complement gene variant were associated with a higher relapse rate. Higher relapse rates have been noted in patients with *CFH* and CD46 mutations whereas those without complement variants seem to have the lowest risk.[70,71] Plasma exchange with immunosuppression is an established treatment for anti CFH antibody HUS—there have been case reports that suggest eculizumab can induce remission in this subtype.

Ravulizumab is a second generation C5 inhibitor modified to enhance endosomal dissociation of C5 and recycling to the vascular compartment through the neonatal Fc receptor pathway.[72] As a result, it achieves inhibition of complement-mediated hemolysis with an extended dosing interval. The terminal half-life is approximately four times that of eculizumab. FDA approval was obtained based on data from 58 adult and 16 pediatric patients with aHUS in single-arm trials. The most serious side effects reported were hypertension, pneumonia, and abdominal pain.

Generally, patients with aHUS who progress to ESRD are considered candidates for transplantation. Living-related donor transplants are not recommended, except possibly in the case of DGKε-associated disease, because of the risk for aHUS in the donor's remaining kidney. There are reports of aHUS developing in family-related renal donors within months of donation.

Since CFH, CFI, factor B, and C3 are soluble plasma proteins, deficiency or dysfunction is not corrected by renal allografting alone. The outcome of renal transplantation in aHUS has been poor, with a high rate of failure due to recurrent disease. In fact, the failure rate can approach 60% to 70% and failure often occurs within the first month after transplantation. The underlying genetic defect is predictive of relapse risk, being as high as 80% with mutations in CFH, C3 and factor B, but as low as 20% in patients with defects in MCP or in those without genetic abnormalities.[73] Before the introduction of eculizumab, combined liver and kidney transplantation was recommended; however the 1-year survival for this complicated procedure was disappointing. Anecdotal reports suggest that eculizumab prophylaxis may prevent post-transplantation recurrence and evidence is accumulating to support such therapy in conjunction with renal allografting.

Going forward, multiple unmet needs remain to be addressed. At this time, diagnosis of aHUS remains a clinical diagnosis of exclusion; generation of a practical assay to affirm a diagnosis of aHUS remains to be developed. Ongoing clinical studies may identify prognostic factors that might help identify which patients could safely discontinue anticomplement therapy, as well as provide informative prognostic data for the family members of patients with identified genetic variants that predispose to development of disease. There are a number of trials with agents targeting C5 incorporating multiple approaches including RNAi, small molecule inhibitors, and long-acting formulations.[74] Unfortunately, agents that target C5 are associated with risk for development of meningococcal disease. C3 inhibitors are also in clinical trials and have demonstrated clinical safety so far. Additional agents that specifically target the alternative pathway though inhibition of either complement factors B or D are also in development.

OTHER THROMBOTIC MICROANGIOPATHIC DISORDERS

Post-Transplantation Thrombotic Microangiopathy

TMA can occur in three transplant-related settings: (1) recurrent disease after transplantation for a TMA-related disorder, (2) in association with the use of immunosuppressive medications (calcineurin inhibitors [cyclosporine A and tacrolimus] and inhibitors of the mammalian target of rapamycin [mTOR inhibitors sirolimus and everolimus]), and (3) after hematopoietic stem cell transplantation.

Recurrent Disease and "De-Novo Thrombotic Microangiopathies" After Renal Transplantation

As indicated above, there is a high risk of developing recurrent aHUS after renal transplantation in patients with disorders of complement regulation. However, it is important to note that the diagnosis of recurrent TMA depends on the correct diagnosis of the index disorder. Patients with suspected de-novo TMA that is subsequently attributed to aHUS may have initially presented with hypertension, renal failure, and nephrosclerosis. In a French series of renal transplant recipients whose initial diagnosis was not aHUS, 7 of 24 of those diagnosed with de-novo aHUS after renal transplantation were shown to have mutations of CFH or CFI. In the majority of these individuals, renal failure was attributed to hypertension or chronic glomerulonephritis. No mutations were identified in a control group of renal transplant recipients who did not develop TMA, suggesting that underlying defects of complement should be considered when TMA develops in the post-renal transplant setting. Prophylactic anticomplement therapy is undertaken prior to transplantation in all patients with complement-mediated TMA due genetic deficiency or dysfunction of CFH or CFI. Some centers use a combination of eculizumab and plasmapheresis. In patients with ESRD due to TMA related to mutations of complement factors produced by the liver (i.e., CFH) a combined kidney liver transplant can correct the ESRD along with the underlying etiology. Most cases of de-novo TMA post-transplant are attributable to drug toxicity (calcineurin inhibitor), rejection, viral infection (such as parvovirus, CMV and hepatitis C), or a combination of these processes. Antibody-mediated rejection (ABMR) may be confirmed by demonstrating the presence of MHC antibody, or by renal biopsy evidence of peritubular capillary C4d staining. In patients with de novo TMA, who were subsequently diagnosed with a genetic mutation or having progressive disease despite addressing reversible causes, anti-complement therapy such as eculizumab is a treatment option. In the absence of anticomplement therapy, plasma exchange every 48 hours can also be performed. In patients found to have a pathogenic mutation, anticomplement therapy may be continued indefinitely. In patients without a pathogenic mutation and who have a precipitating cause, eculizumab discontinuation can be attempted with close monitoring for recurrence.

Immunosuppressive Medications

Cyclosporine, tacrolimus, and sirolimus have been implicated as causes of drug-induced thrombotic microangiopathy. TMA may be more likely to occur with cyclosporine compared to tacrolimus. Cyclosporine A and tacrolimus cause endothelial dysfunction and increased platelet aggregation by inhibiting prostacyclins. In most cases, discontinuation of these agents results in reversal of HUS. In retrospective studies, the incidence of biopsy-proven thrombotic microangiopathy was highest with combination of cyclosporine and sirolimus compared with other regimens and combinations.

Recent evidence suggests that mTor (mammalian target of rapamycin) inhibitors, such as sirolimus and everolimus, can also be associated with post-transplant TMA. It is likely that mTor inhibitors impair endothelial function, but the mechanism remains to be elucidated.

Hematopoietic Stem Cell Transplantation

TMA occurs in approximately 6% of patients who undergo allogeneic bone marrow transplantation; the incidence is estimated to be 0.1% to 1% after autologous marrow or stem cell transplantation. In a prospective study of 77 pediatric patients undergoing a HSCT, 34 patients developed TMA of whom 65% had a genetic variant in at least one gene as opposed to 9% without TMA.[75] Variants in three or more genes was associated with a mortality rate of 71%. The pathophysiology is assumed to reflect systemic endothelial cell injury from a three hit process where patients are susceptible due to a genetic predisposition, undergo stress from the transplant leading to activation of complement and formation of microthrombi leading to end organ dysfunction.

Risk factors include the use of an unrelated or mismatched donor, total body irradiation as part of the pre-transplant conditioning regimen, calcineurin inhibitor treatment, systemic cytomegalovirus or other infection, older age, and graft-versus-host disease (GVHD).

The Overall–TMA criteria by Cho et al uses a broad definition for TMA and incorporates the presence of schistocytes, an elevated LDH, normal coagulation studies, negative Coombs' test result, concurrent renal or neurological dysfunction unexplained by other mechanisms, progressive anemia, thrombocytopenia, and decreased levels of serum haptoglobin.[76] This is coupled with ADAMTS13 levels to distinguish it from TTP. In the pediatric and young adult population, Jodele et al., have proposed a new set of diagnostic criteria incorporating a renal biopsy with an elevated serum LDH, hypertension, proteinuria, new thrombocytopenia, new anemia, presence of schistocytes, and elevated levels of serum concentration of soluble C5b-9 as evidence for terminal complement activation.[77] In general, the diagnosis of HSCT induced TMA (HSCT-TMA) is challenging as fragmented red cells and thrombocytopenia are common after bone marrow transplantation, and because the differential diagnosis of fever, renal failure, and neurologic complications is extensive. The majority of cases occur within the first 100 days with a median of 32 days. Kidneys are a major target organ although it can affect any major organ (Lungs, GI, brain).

The management of HSCT-TMA involves eliminating precipitating factors. This starts with withdrawal or substitution of immunosuppressive medication especially calcineurin inhibitors. Alternative causes should be sought, and aggressive treatment of infection and GVHD should be employed in all but the most overt cases. Plasma exchange while effective in TTP has not been particularly effective in HSCT-TMA with response rates of less than 50%. Among other agents, defibrotide has been used with reported success in a few cases. The mechanism of action is believed to be through the prevention of platelet aggregation and platelet activation in the micro endothelial vasculature. In the pediatric and young adult population, eculizumab has been shown to work with remarkable efficacy in one series, with a 1 year survival of 62% versus 9% in the group treated with other modalities.[78] Patients received a median of 14 doses with all patients discontinuing eculizumab without recurrence of TMA. There have been other efforts to block other mediators of the complement pathway, namely mannose-binding protein-associated serine protease 2 (MASP-2) which when activated cleaves complement proteins C4 and C2 into C4a, C4b, C2a, and C2b. In the clinical trial space, narsoplimab, a MASP-2 inhibitor was evaluated in a phase 2 study for patients with a HUS, TTP, HCT associated TMA. The study met the primary efficacy point showing that 56% of patients receiving at least one dose achieved a complete response to status.

Cancer and Chemotherapy-Associated Thrombotic Microangiopathy

TMA may occur in the course of some patients with disseminated malignant neoplasms and large tumor burdens, most commonly adenocarcinoma of the gastrointestinal tract (mucin producing tumors), breast, or lung. It can occur as a result of bone marrow involvement, metastatic disease or due to a medication used for treatment. Patients generally present with an abrupt onset of moderate to severe MAHA and thrombocytopenia. Renal insufficiency and neurologic dysfunction occur less commonly than in idiopathic or chemotherapy-induced thrombotic microangiopathy and may result from concurrent metabolic disturbances, central nervous system metastases, stroke, or hemorrhage.

Laboratory evidence of DIC is found in 25% to 80% of patients based on findings of elevated fibrin degradation products or more sensitive measures of increased fibrinogen turnover. However, the observation that TMA occurs in only 5% of patients with disseminated malignancy and DIC suggests the involvement of additional factors, such as microvascular occlusion, intimal proliferation induced by tumor emboli within the pulmonary vasculature, or formation of an incompletely endothelialized tumor vasculature that predisposes to platelet adhesion, activation, and aggregation. Direct injury of endothelial vessels from the above processes in the marrow vessels can result in the release of ultralarge VWF multimers. Severe deficiency of ADAMTS13 is not typical. Outcomes of patients who develop TMA in the setting of chemotherapy or advanced cancer are poor because the TMA tends to be unrelenting and the comorbidity of the malignancy is significant. Survival is generally measured in weeks. The only effective therapy is reduction of the tumor burden, a goal often not attainable. A role for plasma exchange has not been established.

Specific cancer chemotherapeutic agents have also been implicated in the development of TMA. Patients are often on therapy for a malignancy at the time TMA develops, making attribution to the neoplasm versus its therapy difficult to determine. However, unlike cancer-associated TMA, most patients with chemotherapy-associated TMA may not have a large tumor burden. Implicated agents include mitomycin-C, gemcitabine, platinum-based chemotherapy, bleomycin, docetaxel, 5-fluourouracil, interferon-α and VEGF inhibitors, immunotherapy either alone or in combination. Chemotherapy-associated TMA is presumed to result from direct toxicity to the endothelium. Mitomycin inhibits the production of prostacyclin by umbilical vein endothelium, and infusion of mitomycin-C into the rat kidney induces histologic changes like those found with chemotherapy-induced TMA. Alternatively, anti-VEGF antibodies and other VEGF inhibitors have revealed a critical dependence of podocytes and glomerular endothelial cells on VEGF. Toxicity of these agents includes a thrombotic microangiopathy localized primarily to the kidney and manifested mainly by hypertension and proteinuria.

Patients with chemotherapy-associated TMA generally present with moderate to severe MAHA, thrombocytopenia, and renal insufficiency. Approximately 15% to 20% of such patients develop neurologic dysfunction. Compared to patients with TTP, cancer associated TMA may have greater pulmonary involvement with pulmonary edema and a new or exacerbated hypertension.

ADAMTS13 levels are normal or mildly reduced in chemotherapy-associated TMA. Plasma exchange has not been shown to be beneficial; however, case series raise the possibility that eculizumab may have utility in gemcitabine associated TMA.

Streptococcus Pneumonia

HUS associated with *Streptococcus* pneumonia occurs mainly in infants and young children, and rarely affects adults. It accounts for between 4% and 5% of all HUS cases United States. The incidence of pneumococcal associated HUS has decreased since the introduction of 13 Valent vaccine.

Several mechanisms have been proposed for the pathogenesis of pneumococcal associated HUS. The prevailing theory used to be centered around N-acetyl neuraminidase (sialidase) which is released during a pneumococcal infection. This cleaves sialic acid on the glycocalyx of the cell. It had been proposed that desialylation by neuraminidase results in the exposure of Thomsen-Friedenreich antigen (T antigen) on platelets, RBCs and glomeruli resulting in agglutination of red cells and hemolysis.[79]

An alternative proposal is desialylation by neuraminidase disrupts CFH binding sites on cell surfaces resulting in unregulated complement activation.[80] More recently, it has been proposed that increased expression of pneumococci surface proteins that bind plasminogen leading to plasmin generation resulting in fibrinogen degradation and complement activation leading to endothelial cell damage.[81]

Disordered Cobalamin Metabolism

Mutations in the MMACHC gene, which results in methylmalonic aciduria and homocystinuria, can result in atypical HUS. Clinically, these patients present with neurocognitive disease from their childhoods have microcephaly, seizures, ataxia, hypotonia, developmental delay, and a diagnosis of atypical HUS.

The diagnosis should be suspected in the presence of megaloblastic anemia accompanied by marked increase of homocysteine and low methionine levels, very high rates of urinary excretion of homocysteine and methylmalonic acid. The diagnosis is confirmed by genetic testing of the *MMACHC* gene.

Therapy includes parenteral administration of hydroxocobalamin, betaine, carnitine supplements, and leucovorin calcium with early initiation being critical for a good prognosis.

Miscellaneous Drug-Associated Thrombotic Microangiopathy

Although TMA has been associated with more than 75 drugs, the nine drugs that account for 75% of the cases include clopidogrel, estrogen/progesterone, gemcitabine, interferon, mitomycin, quinine, tacrolimus, and ticlopidine. The mechanisms by which these agents induce TMA may differ, as may the natural history and response to therapy. Whereas mitomycin C, gemcitabine, and Cyclosporine appear to induce TMA in a cumulative dose-dependent manner, quinidine and thienopyridines (ticlopidine and clopidogrel) induce thrombotic microangiopathy through either idiosyncratic, immune-mediated mechanisms or by acute endothelial toxicity.

The first report of quinine-associated TMA described the course of three patients with a syndrome resembling idiopathic HUS.[82] Patients generally present with severe MAHA, platelet counts below 50,000/μL and renal insufficiency, usually requiring dialysis. Neurologic dysfunction occurs in a minority of patients, but it can be severe; granulocytopenia and lymphopenia have been reported. In earlier reports, the prognosis was favorable once quinine was withdrawn and plasma exchange instituted. However, in another series, 17 of 225 patients with HUS had quinine-associated thrombotic microangiopathy, 4 of whom died, and 7 survivors were left with chronic renal failure.[83] Although this disorder occurs most commonly after the ingestion of quinine tablets, cases have been reported after exposure to quinine in beverages such as tonic water or herbal health supplements (cinchona). A careful history is sometimes necessary to establish the link between quinine ingestion and the patient's clinical disease. The pathogenesis may involve idiosyncratic, quinine-dependent antibodies reactive with platelet glycoproteins IIb/IIIa and Ib/IX and related antigens on endothelial cells and neutrophils that promote neutrophil aggregation and binding to endothelial cells in a drug-dependent manner. Patients with quinine-induced TMA have significant early mortality, though with appropriate supportive care and treatment of the acute episode, the disorder does not recur without re-exposure to quinine.

The thienopyridines are another common cause of drug-induced TTP. TTP occurs in a higher percentage of patients exposed to ticlopidine, with an incidence ranging from 1:600 to 1:4814 patient exposures in contrast to an estimated incidence of 4 per 1,000,000 to 1 per 8500 to 26,000 exposures to clopidogrel. No cases of clopidogrel-associated TTP were encountered in the CAPRIE and CURE studies, each of which enrolled more than 6200 patients. Despite the low incidence, the frequency with which clopidogrel is prescribed rendered it the most commonly reported drug associated with TTP in the FDA MedWatch database, accounting for more than 30% of all cases. The pathogenesis and natural history of TTP associated with ticlopidine and clopidogrel differ. Reductions in ADAMTS13 activity below 15% occur in 85% of patients with ticlopidine-associated TTP but in only 15% of patients with clopidogrel-associated TTP. Reduced ADAMTS13 reflects the development of anti-ADAMTS13 antibodies. TTP generally develops within 2 to 12 weeks of starting ticlopidine and responds relatively quickly to plasma exchange. Spontaneous relapses may occur. In contrast, 90% of patients exposed to clopidogrel, but only 10% of patients exposed to ticlopidine develop a syndrome characterized primarily by MAHA and renal insufficiency, without severe thrombocytopenia; these individuals have normal levels of ADAMTS13, usually develop disease within the first 2 weeks of exposure, and may require several weeks of plasma exchange to achieve remission. Whether or not plasma exchange actually improves the clinical outcome is uncertain. Spontaneous relapses are uncommon.

HIV-Associated Thrombotic Microangiopathy

An association between HIV infection and TMA has been recognized since 1984. TMA occurred in up to 7% of patients hospitalized with HIV infection. Conversely, the incidence of HIV infection in patients with TMA varied from 15% to 50% in endemic areas. In contrast, TMA is rare in HIV patients who are treated with highly active antiretroviral therapy (HAART). The mechanism of disease remains unclear, but endothelial injury has been hypothesized. Coexisting opportunistic infections may be a contributing cofactor. TMA that occurs in patients with advanced or untreated HIV often responds quickly to the initiation of antiretroviral therapy and can relapse if therapy is discontinued.

In some patients with HIV infection, the associated immune dysfunction may predispose to the formation of autoantibodies against ADAMTS13. This can lead to severe ADAMTS13 deficiency and TTP, despite adequate treatment for HIV. These patients may respond to plasma exchange.

Pregnancy-Associated Thrombotic Microangiopathy

The differential diagnosis of MAHA associated with gestation is complex. MAHA is seen in many conditions unique to pregnancy, such as pre-eclampsia, acute fatty liver associated with DIC, and HELLP syndrome (an acronym for *h*emolysis, *e*levated *l*iver function tests, and *l*ow *p*latelet count) in addition to aHUS and TTP.[84] The severity of the renal and neurologic abnormalities, and the time during gestation at which the signs and symptoms of TMA first appear may provide the clues needed to prevent critical delays in therapy.

For patients with congenital severe ADAMTS13 deficiency, pregnancy has a very high likelihood to trigger an acute severe episode, unmasking cTTP. The French TMA Reference Center reported an incidence of 24% of cTTP in pregnant patients presenting with their first TTP episode. For patients with an acquired autoimmune TTP, pregnancy may also increase risk of relapse. The syndrome occurs more commonly in the later half of pregnancy or in the postpartum period. Persistence or worsening thrombocytopenia, MAHA, and end-organ injury after delivery is strongly suggestive of a TMA. Pregnancy is often the first presentation for patients with cTTP. As part of the diagnosis, finding ADAMTS13 activities of less than 10% is crucial (ADAMTS13 levels decrease during pregnancy and may fall below 50% in many pregnant women close to term).

aHUS also occurs with increased frequency in association with pregnancy. The disorder primarily affects primiparas who present with MAHA, thrombocytopenia, renal insufficiency, and hypertension primarily in the postpartum period[85]—this later onset may help to distinguish HUS from other causes of pregnancy-associated MAHA and thrombocytopenia, such as pre-eclampsia and HELLP, which occur late in gestation or soon after delivery. Worsening renal function despite blood pressure control and delivery of the child should raise the suspicion for aHUS. Anticomplement therapy should be initiated promptly to preserve organ function (kidneys) if a complement-mediated process is suspected. Currently, the fetal effects of anticomplement therapy is unknown, but there does not appear to be increased fetal risks. Delivery does not treat complement-mediated TMA and these patients will need continued treatment with anticomplement therapy.

The HELLP syndrome complicates approximately 0.5% to 0.9% of pregnancies and approximately 10% to 20% of cases of pre-eclampsia. The pathogenesis is attributed to aberrant placental development, but the details remain unclear. Patients often present with abdominal pain and/or gastrointestinal symptoms, and concomitant hypertension and proteinuria. Seventy percent of cases occur prior to delivery, and most of the post-partum cases occur within 48 hours of parturition. Diagnosis is based on evident microangiopathic changes on the blood smear, thrombocytopenia, and abnormal liver function studies. The differential diagnosis is broad, and includes acute fatty liver of pregnancy, TTP, aHUS, vasculitis, DIC, and infection. The timing of development of symptoms may assist in the diagnosis because TTP tends to occur earlier in pregnancy, whereas aHUS often occurs post-partum. In one study, ADAMTS13 was decreased but not severely deficient in women with HELLP syndrome, with a reported mean of 31%.[86] Patients with HELLP usually have thrombocytopenia at that is less severe than what is seen in TTP and is usually more than 50,000. In addition, elevated transaminases are more commonly associated with HELLP than with aHUS or TTP. Initial management is to stabilize the patient, treat hypertension and prepare for delivery—delivery is considered curative for HELLP syndrome.

CHAPTER 133

STRUCTURE, BIOLOGY, AND GENETICS OF VON WILLEBRAND FACTOR

Paula James, Orla Rawley, and Mackenzie Bowman

Von Willebrand factor (VWF) is an adhesive multimeric plasma glycoprotein (GP) that mediates platelet adhesion to injured subendothelium via GPIbα, and binds and stabilizes factor VIII (FVIII) in the circulation, protecting it from proteolytic degradation. This important multifunctional protein was named after the Finnish physician Dr. Erik von Willebrand, who first described von Willebrand disease (VWD) in 1926. In the original publication, he described a severe mucocutaneous bleeding problem in a family living on the Åland archipelago in the Baltic Sea.[1] The index case, a young woman named Hjördis, bled to death during her fourth menstrual period at the age of 13. Dr. von Willebrand referred to the condition as *pseudohemophilia*, but noted that in contrast to hemophilia, this condition affected both genders, with females typically being more severely affected.

In the mid-1950s, it was recognized that VWD was usually accompanied by a reduced level of FVIII activity, and that the bleeding phenotype could be corrected by the infusion of normal plasma.[2] In the early 1970s, the critical immunologic distinction between FVIII and VWF was made, and since that time significant progress has been made in our understanding of the molecular pathophysiology of this disorder.[3] Cloning and characterization of the *VWF* gene in the 1980s has facilitated further investigation into the function of VWF and the genetic basis of VWD.[4–7]

FUNCTIONS OF VON WILLEBRAND FACTOR

VWF is a multifunctional adhesive protein that plays an important role in both primary hemostasis and blood coagulation. In primary hemostasis, VWF initiates platelet adhesion at the site of endothelial injury, whereas in coagulation, VWF stabilizes FVIII in the circulation (Fig. 133.1).

Platelet Adhesion

At the site of endothelial injury, VWF adheres to exposed collagen. The hemostatically important forms of collagen include types I, III, and VI, but VWF preferentially binds to type III collagen. The interactions of VWF with collagen are predominately mediated by the VWF A3 domain (Fig. 133.2).[8] Once immobilized, VWF is subjected to the high shear rates of the arterial circulation and undergoes a conformational change that exposes the platelet GPIbα binding site within the VWF A1 domain.[9] High affinity, rapid, and reversible interaction between VWF and GPIbα tethers platelets to the endothelium, where they roll until they are immobilized and activated by direct platelet-collagen binding, which is mediated by two collagen receptors on platelets, GPVI and the integrin α2β1 (or GPIa/IIa).[10,11] The Arg-Gly-Asp (RGD) sequence within the VWF C1 domain also contributes to platelet adhesion by interacting with GPIIb-IIIa of activated platelets.[12]

Factor VIII Stabilization

VWF binds FVIII through the VWF D′D3 domains and protects it from proteolytic degradation, thereby prolonging its half-life. In the absence of VWF, FVIII has a half-life of approximately two hours in contrast to a half-life of 12 to 20 hours when bound to VWF.

BASAL VON WILLEBRAND FACTOR LEVELS

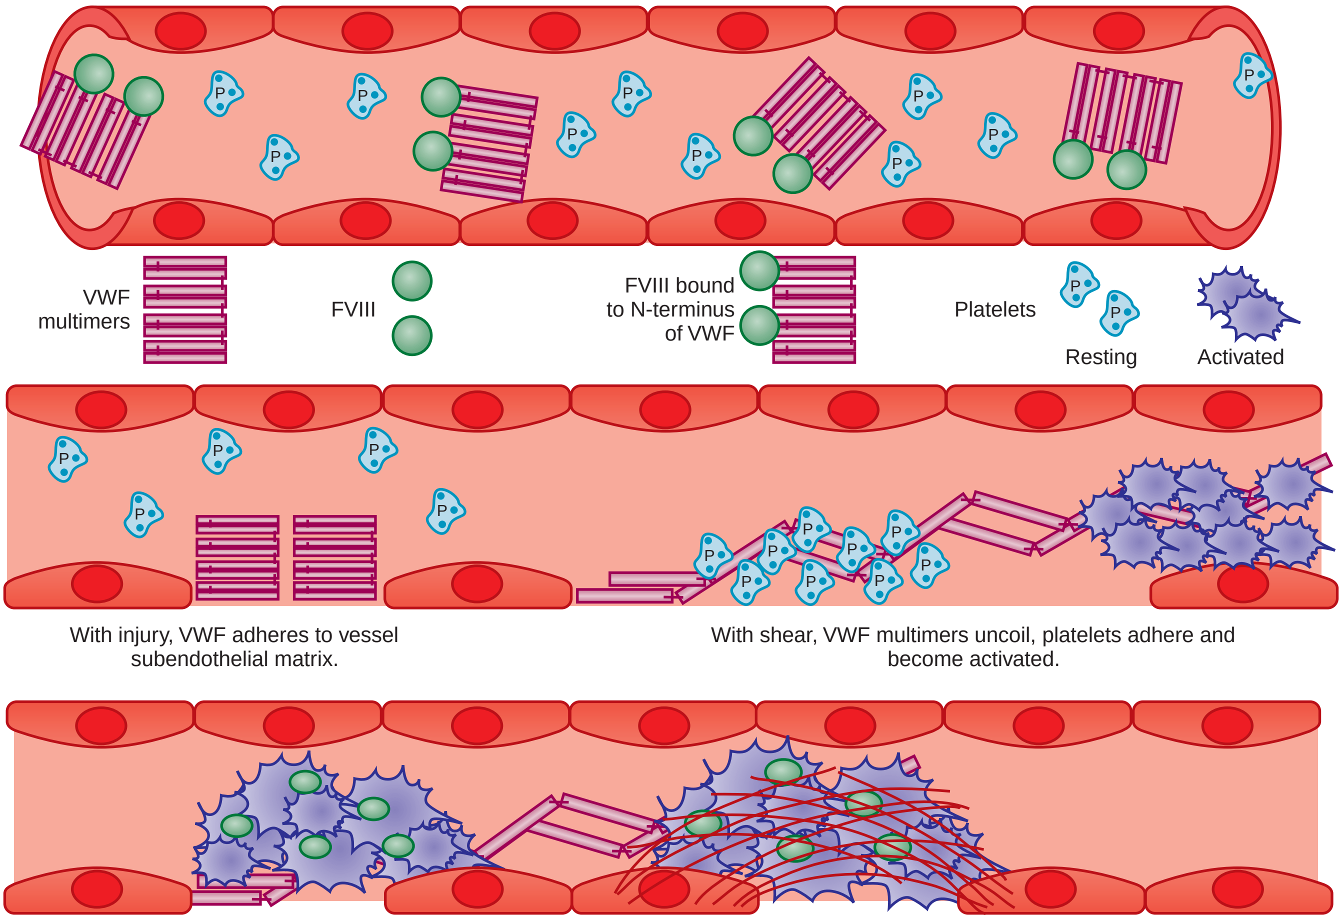
The normal level for VWF is highly variable and ranges from 50 to 200 IU/dL. Factors that contribute to the variable VWF levels include ABO genotype (see section on ABO blood groups later), Secretor genotype, race, and age. Plasma VWF concentrations have been reported to be approximately 20% higher in subjects homozygous for the Secretor (Se) allele as compared with those who are heterozygous.[13] VWF levels in African Americans are 15% higher than in those of European descent. Increased age has also been associated with higher VWF levels,[14] with studies suggesting that the levels may increase by 3.5 IU/dL per decade.[15]

Within individuals, VWF levels often vary over time as a result of β-adrenergic stimuli, drugs, or more sustained physiologic factors, such as pregnancy, hypothyroidism, chronic illness, or long-term use of certain medications.[16,17] The vasopressin analogue, 1-deamino-(8-D-arginine)-vasopressin (DDAVP, desmopressin) transiently and reliably increases VWF and FVIII levels—a fact that, in addition to an acceptable side effect profile, has led to the use of DDAVP as a first-line treatment in certain types of VWD and mild hemophilia A.[18] Several physiologic stressors involving β-adrenergic stimulation, such as exercise, surgery, and psychological distress, can produce an acute increase in VWF levels.[19] VWF levels remain elevated for up to 6 days after surgery, suggesting that after the acute secretory response, there is upregulation of VWF production. A sustained elevation of VWF levels can occur with chronic diseases, such as hyperthyroidism, renal failure, diabetes, liver disease, atherosclerosis, chronic inflammatory states, and cancer.[16,20–23] Conversely, acquired VWD, characterized by qualitative or quantitative VWF defects, can occur with certain medications, such as valproic acid,[24] and with some chronic medical conditions (see section later on acquired VWD).

VWF levels are increased by estrogen.[17] In premenopausal women, VWF levels vary in a cyclical fashion, with the lowest levels occurring in the early follicular phase of the menstrual cycle (days 1 to 7), and peak values occurring during the luteal phase. Oral contraceptives increase VWF levels and dampen the cyclical variation. This dose-dependent effect is mediated by the estrogen component and is evident with ethynylestradiol doses of 0.5 μg or higher. Lower estrogen doses have little or no effect on VWF levels. VWF levels increase in pregnancy starting in the second trimester and achieve levels threefold higher than baseline values by the end of the third trimester.[25] VWF levels return to baseline 1 to 3 weeks after delivery.

VON WILLEBRAND FACTOR GENE

Located on the short arm of chromosome 12 at p13.3, the *VWF* gene spans 178 kb and is composed of 52 exons that range in size from 1.3 kb (exon 28) to 40 bp (exon 50) (see Fig. 133.2A). There is a partial, unprocessed pseudogene, *VWFP*, located on the long arm of chromosome 22 at q 11.2, measuring 21 to 29 kb, which duplicates the *VWF* gene sequence for exons 23 to 34 with 97% sequence homology.[26] Gene conversion events involving the pseudogene contribute to the variant spectrum of VWD. The *VWF* gene is highly polymorphic. Analysis of the 1000 Genomes database has revealed more than 2700 single nucleotide variants (SNVs) in the normal population alone.[27] These variants are found throughout the coding



With injury, VWF adheres to vessel subendothelial matrix.

With shear, VWF multimers uncoil, platelets adhere and become activated.

Activated platelets expose phosphatidyl serine and bind FVIII to facilitate clotting.

Bleeding ceases by platelet-fibrin plug sealing vascular injury and is followed by thrombolysis and tissue repair.

Figure 133.1 FUNCTION OF VON WILLEBRAND FACTOR (VWF). Role of VWF in mediating the initial events in the hemostatic process. VWF is the carrier protein for FVIII *(top)*. After endothelial injury, VWF adheres to the exposed subendothelium, where it is uncoiled by the shear forces, thereby exposing GPIbα binding sites that interact with platelets *(middle)*. The bound platelets are activated and the GPIIb-IIIa complex is exposed on the platelet surface. Interaction of fibrinogen and VWF with GPIIb-IIIa then consolidates the platelet adhesive event and initiates platelet aggregation *(bottom)*. *FVIII*, Factor VIII; *GP*, glycoprotein. *(Used with the permission of Robert Montgomery.)*

sequence as well as in intronic regions, and appear to occur at a rate of ~2.5 variants per individual. The majority of these are rare variants, the pathological significance of which remain unclear, but a significant portion are associated with non-synonymous coding sequence changes, splice site changes or insertion/deletions. An International Society on Thrombosis and Haemostasis Scientific and Standardization Committee (ISTH-SSC) database of both benign and pathogenic variants is maintained by the European Association for Haemophilia and Allied Disorders (https://dbs.eahad.org/upcoming-vwf-db/). The high degree of polymorphism, the large size, and the presence of the pseudogene render full *VWF* gene sequencing and data interpretation challenging.

VWF expression is tightly restricted to endothelial cells and megakaryocytes. Cell-specific transcriptional regulation is complex and poorly understood. A 734-base pair region, spanning approximately 500 bases of the 5′-flanking region and 247 bases of the first exon, functions as a promoter and includes a minimal core promoter, as well as negative and positive regulatory regions.[28] The positive regulatory region confers cell-specificity by relieving inhibition in specific cells, thereby allowing transcription of the *VWF* gene.

DOMAIN STRUCTURE

Encoded VWF messenger ribonucleic acid is 8.8 kb in length and the translated pre-pro-VWF molecule contains 2813 amino acids (AA), comprising a 22 AA signal peptide, a 741 AA propeptide, and a 2050 AA mature subunit that possesses all the adhesive sites required for hemostatic activity. The AA sequence is cysteine rich, with cysteine residues constituting 8.3% of the total amino acid content. Cysteine residues are mainly found clustered in the N- and C-termini where they are involved in extensive intra- and inter-molecular disulfide bonding. Cysteines are least abundant in the VWF A domains, which contain just six cysteine residues. Both the A1 and A3 domains take on the form of disulfide-bonded loops, while the A2 domain possesses a rare vicinal disulfide that contributes to domain stability.[29]

The VWF AA sequence exhibits considerable internal homology and comprises a series of repeated domains (A, C, and D), which make up approximately 90% of the precursor. These repeated domain structures are highly homologous to domain structures found in many unrelated proteins. For example, the VWF A domain is the prototype for a protein superfamily and appears in up to 22 human proteins, such as leukocyte adhesion receptors, collagen receptors, and cartilage matrix protein.[30] Likewise, homologues of the VWF C, D, and cysteine knot (CK) domains exist throughout the genome and are found in proteins with various functions. This suggests that the *VWF* gene is the product of a complex series of partial gene duplications.

Based on the homologous internal repeat structure, the domain composition of VWF is given as NH2-SP-D1-D2-D'-D3-A1-A2-A3-D4-C1-C2-C3-C4-C5-C6-CK-COOH.[31] The D domains are further divided into VWD, C8, TIL, and E subdomains. D' is a truncated assembly containing only the TIL and E subdomains. The D1,

Figure 133.2 VON WILLEBRAND FACTOR GENE, PRIMARY TRANSLATIONAL PRODUCT AND PROTEIN. (A) The *VWF* gene is located on chromosome 12 at p13.3, spans 178 kb and includes 52 exons. The *VWF* pseudogene is located on chromosome 22 and replicates exons 23 to 34. The VWF mRNA is 8.8 kb in length. Pre-pro-VWF contains 2813 amino acids (AA) with a 22-AA signal peptide, a 741-AA propeptide, and a 2050-AA mature subunit. (B) The mature subunit consists of repeated domains (A–D), several of which have distinct functions and binding sites. *ADAMTS13*, A disintegrin and metalloproteinase with a thrombospondin type I motif member 13; *FVIII*, factor VIII.

D2, and D3 assemblies comprise VWD, C8, TIL, and E subdomains, while the D4 assembly lacks the E subdomain, but carries a unique subdomain structure designated D4N (see Fig. 133.2B).

The functional significance of many of the individual VWF domain structures has been established. The signal peptide (S) targets pre-pro-VWF to the endoplasmic reticulum (ER), where it is promptly cleaved. The CK domains of adjacent VWF monomers form disulfide bonds, resulting in tail-to-tail dimers that initiate the multimerization process.[32] The VWF propeptide (D1D2) plays a critical role in VWF multimer assembly by promoting the formation of head-to-head oligomers via intermolecular disulfide bonding between D3 domains of adjacent VWF dimers.[33,34]

Several functional sites that are critical for the regulation of hemostatic activity have also been identified. The D′D3 assembly constitutes the FVIII interactive region of VWF, with the bipartite FVIII binding site encompassing the noncontiguous TIL′ and C8-3 subdomains.[35] The hemostatically active A domains comprise several key binding and regulatory sites. Binding sites for platelet GPIbα, heparin, and collagens I, III, and VI have been localized to the A1 domain, though the major collagen III binding site localizes to the A3 domain.[8,36,37] The A2 domain contains the cryptic cleavage site for the regulatory protease ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13), with the scissile bond located between Tyr1605-Met1606.[38] The platelet GPIIb/IIIa binding site is found within the RGD motif of the C4 domain.[12]

BIOSYNTHESIS

VWF is exclusively synthesized in endothelial cells and megakaryocytes and undergoes a complex series of co- and post-translational modifications, including dimerization, glycosylation, sulfation, and ultimately, multimerization. The fully processed protein is then either released into the circulation or is stored in specialized organelles: the Weibel-Palade bodies (WPBs) of endothelial cells or the α-granules of platelets.

Dimerization of pro-VWF monomers occurs in the ER through the formation of disulfide bonds between CK domain monomers in a tail-to-tail fashion. The location of these intersubunit disulfide bonds has been localized to a subset of cysteine residues (Cys2771, Cys2773, and/or Cys2811).[32] In addition, the signal peptide is cleaved and most of the intrachain disulfide bonds are formed in the ER. Only pro-VWF dimers are then transported to the Golgi apparatus. Exiting the ER appears to be the rate-limiting step in VWF biosynthesis.

In the Golgi, pro-VWF dimers make up the basic building blocks for further multimerization. Here, the propeptide (D1D2) is cleaved by a propeptide processing protease, likely furin, between AA 763 to 764. The propeptide continues to be essential for VWF multimerization because under acidic conditions, it serves as an endogenous chaperone that promotes additional disulfide bond formation between D3 domains of adjacent dimers in a head-to-head orientation.[34,39,40] The inter-subunit disulfide bonds are likely mediated by the alignment of the cysteine pairs Cys1099 and Cys1142.[41] The VWF subunit is approximately 250 kDa, whereas resulting disulfide-linked multimers can be more than 20,000 kDa.

The mature VWF subunit is heavily glycosylated with the carbohydrate component making up approximately 20% of the monomeric mass. VWF expresses both N- and O-linked glycan structures which are important regulators of its functional activity, modifying its plasma half-life as well as its susceptibility to regulatory proteolysis by ADAMTS13.[42] In the ER, N-linked glycosylation begins as a co-translational event and 13 N-linked high-mannose-containing oligosaccharide chains are added to each VWF subunit. In addition, the propeptide has four potential N-glycosylation sites. The mannose-rich core is remodeled by a series of glycosyltransferases and glycosidases as the protein transits the ER, facilitating interaction with resident ER chaperones that direct protein folding and subsequent dimerization. Dimerization is absolutely dependent on the addition of N-linked glycans.[43]

Post-translational modification occurs in the Golgi with the addition of 10 O-linked oligosaccharides to the pro-VWF dimer. O-linked glycans are assembled via sequential addition of monosaccharide units rather than by transfer of a preassembled core. N-linked glycans undergo further processing to produce complex-type carbohydrate structures and sulfation of specific N-linked glycans (Asn1147 and Asn1231) occurs in the trans-Golgi network. Finally, both the N- and O-linked glycan structures are modified with capping terminal sialic acid moieties and unusually, approximately 13% of the N-linked and 1% of the O-linked glycans are modified to express ABO(H) antigenic determinants. Overall, the VWF glycome represents an extremely heterogeneous population of sugars. To date, over 300 distinct VWF N-linked glycan structures alone have been described.[44]

Interestingly, platelet-VWF exists as a natural glycoform and has distinct functional characteristics.[45] Terminal sialic expression on the N-linked glycans of platelet-VWF is reduced twofold and although H-antigen expression is comparable to that of its plasma-derived counterpart, further modification of the H antigen to produce group A or B determinants does not occur. As a direct consequence of its differential glycosylation, platelet-VWF is significantly more resistant to ADAMTS13-mediated proteolysis than plasma-derived VWF.

STORAGE AND SECRETION

The majority of the VWF in endothelial cells consists of low-molecular-weight (LMW) multimers that are constitutively secreted. The more biologically active high-molecular-weight (HMW) VWF multimers are preferentially targeted for storage in endothelium-specific cytoplasmic granules, the WPBs. The biogenesis of WPBs is driven by VWF itself. In addition to VWF and the VWF propeptide (VWFpp), numerous other proteins that are essential to hemostasis and inflammation, and to modulation of vascular tone and angiogenesis, are stored in WPBs including P-selectin, CD63, interleukin-8 (IL-8), tissue plasminogen activator, and angiopoietin-2 (Ang-2).[46] WPBs have a characteristic cigar-like shape, measuring 0.2 μm in width and 5 μm in length (Fig. 133.3), and are composed of tightly packed tubules, measuring 150 to 200 Å in cross-section.[47] Platelet VWF is stored within similar tubules that are found in the periphery of α-granules, and constitutes approximately 15% to 20% of total circulating VWF. Tubular packing condenses the length of VWF multimers by 50-fold and is dependent on the acidic pH within the trans-Golgi, as well as the propeptide (D1D2) and the NH_2-terminal region (D′D3A1). Large VWF multimers, which can be up to 100 μm in length, are reversibly packaged into coils. Upon WPB exocytosis, the filamentous strings of VWF are secreted into the circulation, where they rapidly unfurl and are capable of binding to platelets. If the tubular structure is perturbed, WPBs release short, tangled VWF that does not support platelet binding to the endothelium.

VWF is secreted via three pathways—constitutive, basal, and regulated release.[48] Regulated VWF release is via an acute pathway that is triggered by agonist-mediated activation of the endothelium. Basal secretion from WPBs occurs continuously and is likely in response to background levels of agonists and, possibly, also due to mechanical stimulation from the circulating blood. The continuous basal release of VWF is likely to be the source of circulating plasma VWF, whereas the acute regulated release of VWF provides a localised dose of ultra-large VWF (UL-VWF) to initiate primary hemostasis at times of injury.

A variety of agonists can induce the secretion of VWF from endothelial cells.[46] These agonists include histamine, thrombin, fibrin, the terminal complement proteins C5b-9, and β-adrenergic agonists. These agonists work via two main pathways to raise the intracellular levels of either (1) Ca^{2+} or (2) cyclic adenosine monophosphate (cAMP). Upon endothelial stimulation, WPBs release their contents through one of three modes of exocytosis, depending on the type and amount of protein that is required. VWF is released via full fusion of WPB with the plasma membrane. The freshly secreted unusually large, or UL-VWF, multimers are highly active and can spontaneously bind platelets. Some of the released protein remains associated with the endothelial membrane and some self-associates.

ADAMTS13

ADAMTS13 is a constitutively active plasma protease that cleaves circulating VWF between Tyr1605-Met1606 in the A2 domain.[49] Its main target is the UL-VWF multimers, which spontaneously bind platelet GPIbα. ADAMTS13 cleaves UL-VWF multimers when there is sufficient shear-stress to unfold the A2 domain to expose the cryptic cleavage site.[50] UL-VWF multimers that appear in plasma after WPB secretion are cleaved within 2 hours by ADAMTS13 to form LMW, or less hemostatically active multimers. ADAMTS13-mediated proteolysis of VWF is

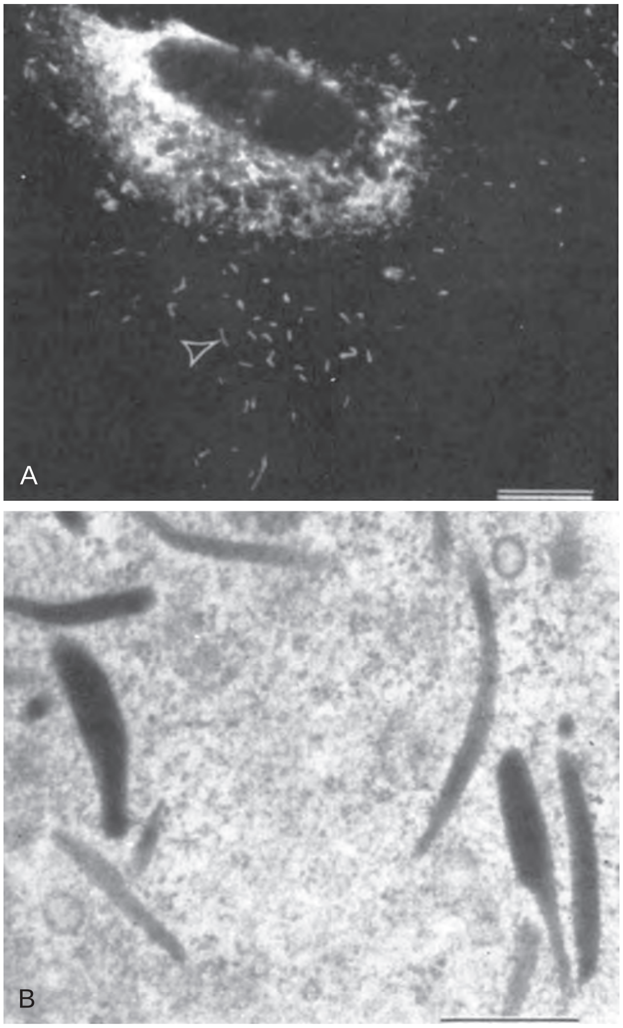

Figure 133.3 WEIBEL-PALADE BODIES OF ENDOTHELIAL CELLS. (A) Immunofluorescence staining of a human umbilical vein endothelial cell (HUVEC) with anti-VWF antibody. VWF is present in the perinuclear region, where it is synthesized, and in the Weibel-Palade bodies *(arrowhead)* throughout the cytoplasm. Bar = 10 µm. responsible for the characteristic "triplet" pattern of the satellite bands that flank each main multimer band on multimer analysis gels (Fig. 133.4).

Susceptibility to ADAMTS13 proteolysis is influenced by glycosylation and specific VWF sequence variants.[51] De-glycosylated plasma-derived VWF is proteolyzed more rapidly than fully glycosylated VWF, and blood group O VWF is cleaved more rapidly than non-O VWF in the order O ≥ B ≥ A ≥ AB. Moreover, Bombay-VWF is proteolyzed even more rapidly than group O VWF.[52] In addition, although terminal α2–6 linked sialic acid expression protects VWF from spurious proteolysis by plasma cysteine and serine proteases, it specifically targets VWF for proteolysis by ADAMTS13.[53] Single-nucleotide variants, such as the c.4751 A > G variant giving rise to p.Tyr1584Cys in the VWF A2 domain, have also been shown to affect the susceptibility of VWF to proteolysis.[54]

Alterations in the balance between ADAMTS13 activity and VWF proteolysis can lead to several disease states. Congenital or acquired deficiency of ADAMTS13 can result in thrombotic thrombocytopenic purpura (see Chapter 132). Conversely, enhanced proteolysis can give rise to a bleeding phenotype. For example, in a subtype of type 2 A VWD, variant VWF exhibits enhanced susceptibility to ADAMTS13 cleavage which results in loss of large VWF multimers.

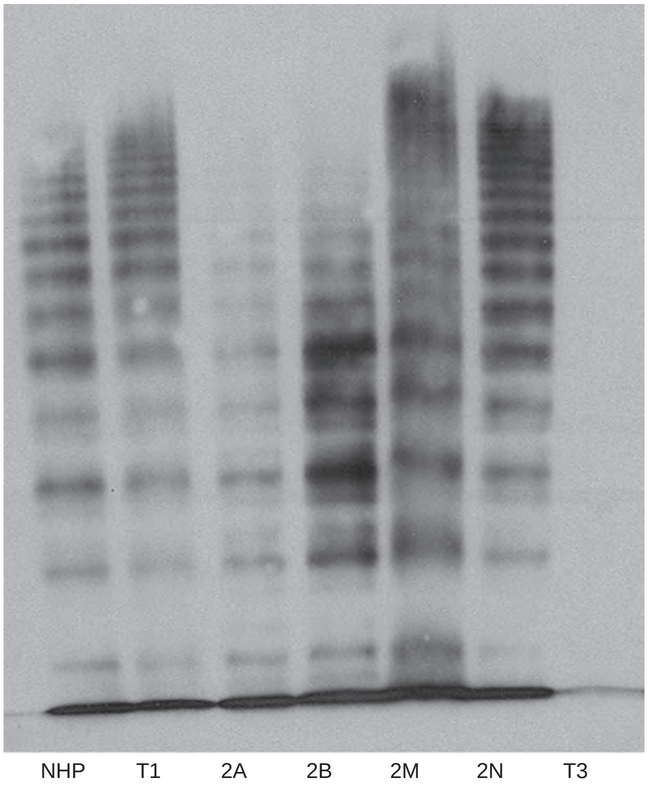

Figure 133.4 EXAMPLE OF A MULTIMER ANALYSIS (2.25% AGAROSE GEL). Lane 1 normal human plasma (NHP) represents normal plasma multimer patterns with a characteristic "triplet" pattern of satellite bands flanking each main multimer. Lanes 2 to 7 show the plasma von Willebrand factor (VWF) multimer analysis for patients with the different subtypes of von Willebrand disease (VWD) (T1, type 1; 2 A, type 2 A; 2B, type 2B; 2 M, type 2 M; 2 N, type 2 N; T3, type 3). Type 2 A and type 2B VWD both show variable loss of high-molecular-weight multimers. Types 1, 2 M, and 2 N demonstrate the presence of high-molecular-weight multimers. Finally, with type 3 VWD, there is a complete absence of VWF.

CLEARANCE

VWF clearance is a complex multifactorial process that involves numerous endocytic receptors expressed on a variety of cell-types.[55] Hepatic and splenic macrophages, as well as sinusoidal endothelial cells, represent the cell types thought to contribute most significantly to VWF clearance, though hepatocytes also have an established role. Following the identification of the asialoglycoprotein receptor (ASGPR) as the first receptor capable of mediating VWF removal from the plasma, several additional VWF clearance receptors were described. Macrophage receptors LRP1, SR-AI, MGL, and endothelial receptors CLEC4M, stabilin-2 and SCARA5 have all been shown to bind and endocytose VWF.[56–62] Although the exact molecular mechanisms underlying each of these VWF clearance pathways have not been fully elucidated, it is clear that both glycosylation and *VWF* sequence variation modulate VWF uptake. Blood group O individuals (see the following section on ABO Blood Groups) exhibit increased VWF clearance compared to non-O blood types displaying shorter VWF survival following DDAVP administration.[63] Additionally, a growing number of missense sequence variants have been associated with accelerated VWF clearance. To date >30 variants have been described. Most of these cluster around the VWF D3 and A1 domains, but variants have been described throughout the entirety of the coding sequence. Accelerated clearance has been associated with type 1, type 2 A, and type 2B phenotypes.

The VWFpp is co-secreted with mature VWF in a 1:1 stoichiometric ratio. After secretion, the VWFpp dissociates from VWF and circulates with a half-life of 2 to 3 hours.[64] In contrast, VWF circulates with a half-life of approximately 12 to 20 hours. These discordant clearance rates mean that the ratio between VWFpp and VWF can be used as a surrogate marker for altered VWF clearance.[65] A ratio >2.2 is considered indicative of accelerated or pathological VWF clearance.

ABO BLOOD GROUPS

ABO blood groups differ only with respect to a single terminal sugar residue. Despite this relatively minor modification to the glycan chain, ABO blood group expression has a significant quantitative effect on plasma VWF levels.[55] Blood group O individuals have plasma VWF levels that are on average 25% lower than those with non-O blood types: the mean VWF level in blood group O subjects is 74.8 IU/dL as compared to 105.9 IU/dL, 116.9 IU/dL, and 123.3 IU/dL in blood group A, B, and AB subjects, respectively.[63] Plasma VWF levels are further reduced in individuals with the rare Bombay phenotype.[52] An accumulating body of evidence suggests that differential VWF clearance is responsible for this quantitative effect, though the receptor responsible for mediating this phenomenon has not been identified. Blood group O individuals have a significantly shorter VWF half-life following DDAVP infusion compared to non-O individuals (Group O vs non-O: 10.0 vs 25.5 hours respectively). In addition, group O individuals also have significantly elevated VWFpp/VWF:Ag, indicating an increased rate of VWF clearance.[65] Clinically, the ABO-related variance in VWF levels is relevant; patients with blood group O are significantly overrepresented in "low VWF" or type 1 VWD populations.[66,67] However, in laboratory practice, blood group stratified VWF reference ranges are not employed.

AREAS OF ONGOING INVESTIGATION

The role of VWF in the regulation of vascular endothelial growth factor-dependent angiogenesis is an ongoing area of investigation. Such regulation occurs directly through its interaction with integrins on endothelial cells and, indirectly, via regulation of WPB formation, secretion of Ang-2, and other constituents.[68] Accumulating evidence suggests that VWF may regulate several aspects of cancer cell biology including tumor metastasis.[69] Additionally, the functional role of VWF in mediating venous thrombosis is an active area of investigation, particularly in the context of pathological immunothrombosis.[70,71] Genome-wide association studies (GWAS) over the past decade have identified a number of variants in non-*VWF* loci that influence plasma VWF levels. These include *STAB2* (stabilin-2), *SCARA5* (scavenger receptor class A member 5), *TC2N* (tandem C2 domains, nuclear), *STXBP5* (syntaxin-binding protein 5), *STX2* (syntaxin-2), and *CLEC4M* (C-type lectin domain family 4 member M).[72] The majority of these are either genes that modify VWF glycosylation, secretion from endothelial cells or platelets, or clearance from the plasma. Studies are currently investigating the effect of these genes on VWF pathobiology.

VON WILLEBRAND DISEASE

VWD is caused by deficient, or defective, plasma VWF and represents the most common inherited bleeding disorder. Bleeding symptoms reflect the defect in primary hemostasis: mucocutaneous bleeding, especially epistaxis and heavy menstrual bleeding. When FVIII levels are sufficiently low, the bleeding phenotype overlaps with that of mild to moderate hemophilia; patients may experience joint or muscle bleeds. The current VWD classification recognizes three types.[73] Type 1 VWD is characterized by quantitative deficiency of VWF, type 2 VWD is characterized by qualitative defects, and type 3 VWD is characterized by an almost complete absence of VWF.

Epidemiology

VWD is the most common inherited bleeding disorder. However, because VWF levels are variable in the population and symptom severity ranges from infrequent, mild bleeding to frequent or severe bleeds, the reported prevalence depends on the diagnostic criteria and the study population. In two large epidemiologic studies, the prevalence of VWD was approximately 1% in healthy school-age children based on low VWF activity, and a personal and family history of bleeding symptoms.[74,75] The prevalence of VWD in individuals who present to a primary care physician with bleeding symptoms is approximately 0.1%,[76] whereas in patients whose bleeding symptoms are sufficiently severe to warrant referral to specialized centers, the prevalence is 20 to 113 per million.[77]

Classification and Pathophysiology

The 2006 International Society on Thrombosis and Haemostasis (ISTH) VWD classification relies on the VWF protein phenotype, which in turn often reflects the underlying pathophysiology and has implications for treatment.[73] Type 1 VWD is a partial quantitative deficiency; type 2 (with four subtypes: 2A, 2B, 2M, and 2N) is a qualitative defect; and type 3 is a virtual deficiency of VWF (Table 133.1). The diagnosis and categorization of VWD into types can be achieved with laboratory testing. The differentiation among type 2 subtypes may require referral to a specialized laboratory. The current classification does not incorporate genotypic data: the diagnosis of VWD is not limited to individuals with variants within the *VWF* gene. *VWF* sequence variants may not be identified in VWD patients because of the complexity of the *VWF* gene or because of variants in other genes, such as those affecting secretion or clearance, which also lead to a VWD phenotype. A third level of classification denoted by roman numerals (e.g., VWD type 2A IIA) indicates specific phenotypes, and is a remnant of an older classification system that is mainly used in the research setting.

The American Society of Hematology (ASH), the ISTH, National Hemophilia Foundation (NHF), and the World Federation of Hemophilia (WFH) are currently collaborating to develop guidelines for the diagnosis and management of VWD. These guidelines, once finalized, will provide clinicians with an up-to-date consensus on VWD.

Von Willebrand Disease Type 1

Type 1 VWD, a quantitative deficiency of VWF, represents approximately 70% of VWD cases. The VWF is functionally normal, and patients have normal VWF multimers. Functional assays of VWF, such as VWF:RCo, are decreased in proportion to the decrease in

TABLE 133.1 **Classification of von Willebrand Disease**

Type	Description
1	Partial quantitative deficiency of VWF. Mild abnormalities in multimer structure or distribution may occur.
2	Qualitative VWF defects.
2A	Decreased VWF-dependent platelet adhesion and deficiency of HMW VWF multimers.
2B	Increased affinity for platelet GPIbα.
2M	Decreased VWF-dependent platelet adhesion with a normal multimer distribution.
2N	Decreased affinity for FVIII.
3	Almost complete deficiency of VWF.

FVIII, Factor FVIII; *GPIbα*, glycoprotein Ibα; *HMW*, high molecular weight; *VWF*, von Willebrand factor.

VWF:Ag, and the ratio of functional activity as compared with VWF:Ag is normal (i.e., VWF:RCo/VWF:Ag ratio is >0.7).

Sequence variants have been identified in approximately 65% of individuals with type 1 VWD and occur throughout the *VWF* gene.[78–80] Fully penetrant, dominantly inherited missense variants are more often identified when VWF:Ag and VWF:RCo levels are less than 25 IU/dL. In contrast, incompletely penetrant, dominantly inherited missense variants, such as p.Tyr1584Cys and p.Arg924Gln, are identified in approximately 50% of individuals whose VWF:Ag and VWF:RCo levels are above 25 IU/dL. The extent to which incompletely penetrant *VWF* variants contribute to the bleeding phenotype in individuals with VWF levels of approximately 50 IU/dL is not clear, and genetic analyses in such cases are difficult to interpret.

Missense variants may affect VWF levels by reducing secretion and/or increasing clearance. The most frequently reported genetic variant is a missense variant that results in the substitution of tyrosine with cysteine at amino acid 1584 (p.Tyr1584Cys), which is found in 10% to 20% of type 1 VWD patients.[67] Intracellular retention is a common mechanism for type 1 VWD pathogenicity, and can result from missense variants in various VWF domains. Haploinsufficiency from a heterozygous null allele results in reduced VWF expression in a small proportion of cases. A common heterozygous in-frame large deletion of exons 4 and 5 was reported in a cohort of type 1 VWD patients in the United Kingdom,[81] and this, and similar partial gene deletions, may contribute to the spectrum of variants in a minority of cases. A well-described pathophysiologic mechanism for type 1 VWD is increased VWF clearance, referred to as type 1 C (C for increased clearance), although this designation is not included in the ISTH classification. Patients typically have very low VWF levels, an increased VWFpp/VWF:Ag ratio, and a marked but short-lived response to DDAVP.[55,82] Of note, the half-life of VWF/FVIII concentrates is normal in these individuals. Missense variants mainly cluster around the D3 and A1 domains and can reduce the half-life of VWF up to 15-fold. p.Arg1205His, which is known as the "Vicenza" variant, is the most common, most severe, and best characterized of these variants.[83] Because of the transient response to DDAVP, the utility of this medication for treatment of major bleeds is questioned in this subgroup of patients.

VWF levels increase with age in normal individuals and the same phenomenon is seen in patients with type 1 VWD (but not type 2 or 3).[84] The increase has been reported as 3.5 IU/dL VWF:Ag and 7.1 IU/dL FVIII:C per decade. The effect of this increase on bleeding phenotype remains unclear and requires further investigation.

Von Willebrand Disease Type 2

Type 2 VWD is characterized by a qualitative defect of VWF activity and is further classified into subtypes that affect VWF-platelet interactions (2 A, 2B, and 2 M) and that affect VWF binding to FVIII (2 N) (Fig. 133.5).

Type 2A

Type 2A VWD is the most common type 2 subtype, accounting for approximately 10% of all VWD cases. Type 2 A VWD is usually inherited as a dominant trait and is characterized by a lack of HMW and/or intermediate-molecular-weight (IMW) multimers, which are the most hemostatically active. This results in a disproportionately low functional activity compared with the antigen level (i.e., VWF:RCo/VWF:Ag ratio of <0.7). The FVIII level may be low or normal. The multimer profile shows a loss of HMW and sometimes IMW multimers. This subtype may encompass missense variants that impair dimer (CK domain) or multimer assembly (recessive variants in the D1 and D2 domains), disrupt intersubunit disulfide bonds (D3 and D2 domains), enhance susceptibility to ADAMTS13-mediated proteolysis (A2 and A1 domains), and/or result in intracellular retention of VWF, particularly the HMW multimers (D3, A1, and A2).[85]

Type 2B

Type 2B VWD is the result of gain-of-function variants within the GPIbα binding site on VWF. Missense variants are in exon 28, in or close to the A1 domain. This results in spontaneous binding of VWF to platelets without the need for a VWF-collagen interaction. The VWF-platelet interactions selectively deplete the HMW multimers by increasing ADAMTS13 proteolysis. The increased binding of mutant VWF to platelets also triggers the formation of platelet aggregates, which are removed from the circulation resulting in thrombocytopenia. Altered megakaryocytopoiesis characterized by giant platelets with abnormal ultrastructure contributes to the thrombocytopenia.

The laboratory profile reveals a decreased VWF:RCo/VWF:Ag ratio and absence of HMW multimers, but in contrast to Type 2 A, ristocetin-induced platelet aggregation (RIPA) reveals increased sensitivity to low doses of ristocetin. Although these features may be present to varying degrees in the majority of patients, not all cases

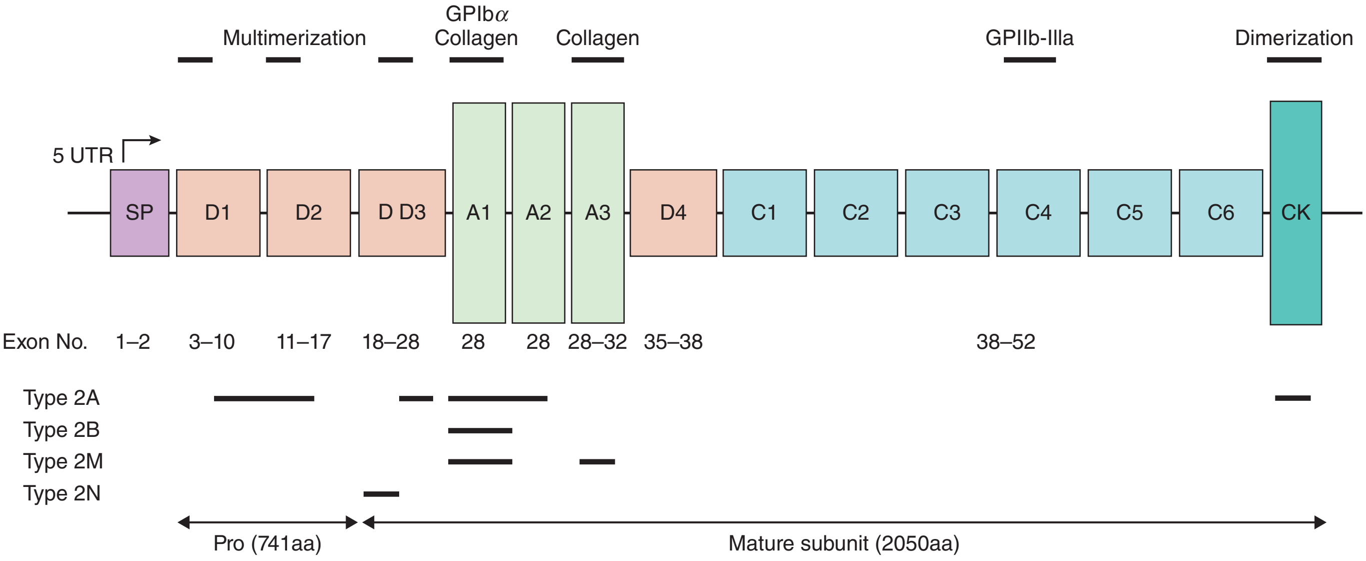

Figure 133.5 FUNCTIONAL DOMAINS OF VON WILLEBRAND FACTOR AND LOCATION OF TYPE 2 VON WILLEBRAND DISEASE (VWD) VARIANTS. VWF protein comprises a large N-terminal propeptide and mature subunit. Repeated protein domains are designated A through D. Highlighted are binding sites for factor VIII, platelet GPIb, collagen, and the areas critical for dimerization and multimerization. Sites of the common variants that result in type 2 VWD are shown. *Arrow* indicates translational start site. *FVIII*, Factor VIII; *GP*, glycoprotein; *VWF*, von Willebrand factor.

demonstrate these classic features. For example, variants affecting p.Pro1266Leu may enhance GPIbα binding (RIPA) without inducing thrombocytopenia or HMW multimer loss.[86]

Type 2M

Type 2M VWD (the M refers to multimer) is characterized by a loss of function variant within the VWF GPIbα binding site. The laboratory workup shows a reduced ratio of VWF:RCo to VWF:Ag, but a normal multimer pattern. A number of missense variants are reported in exon 28, and there are case reports of variants in exons 27, 30 to 31, and 52. VWF exhibits reduced affinity for GPIbα because of variants in the A1 domain that alter protein conformation,[87] but the HMW multimers are normal. Rare variants in the A3 domain that impair the VWF-collagen interaction are also classified as 2M VWD.[88] In these cases, VWF:RCo may be normal, and the diagnosis requires VWF collagen binding assays (VWF:CB).

Type 2N

Type 2N VWD (the N referring to Normandy, where the first cases were reported) has been described as an autosomal form of hemophilia A, and is an important consideration in the differential diagnosis of individuals of either sex who present with low FVIII levels.[89] The affinity of VWF for FVIII is reduced because of variants in the FVIII binding site, or conformational changes that impair the VWF-FVIII interaction. The characteristic laboratory feature is a disproportionate decrease in the FVIII level relative to the VWF level (which may be low or normal) with a resultant reduction in the FVIII:C/VWF:Ag ratio. The majority of patients with VWD type 2N have a normal multimer profile, but occasional cases will demonstrate loss of HMW multimers. The majority (≈ 80%) of missense variants are located in exons 18 to 20 (D′ and D3) with a much lower proportion of variants in exons 17 and 24 to 27. Type 2N exhibits autosomal recessive inheritance, and affected individuals are either homozygous, compound heterozygous for missense variants, or compound heterozygous for a missense variant and a variant resulting in a null allele. Definitive diagnosis requires evidence of reduced FVIII binding to VWF (VWF:FVIIIB) or identification of causative variants in the FVIII binding region of the *VWF* gene.

Von Willebrand Disease Type 3

Type 3 VWD is defined by a virtual absence of VWF. The inheritance of type 3 VWD is autosomal recessive in about half of type 3 patients and autosomal codominant in the remainder: approximately 50% of carriers will be symptomatic and meet the criteria for type 1 VWD.[90] This condition is characterized by prolongation of the aPTT, undetectable levels of VWF:Ag and VWF:RCo, and FVIII levels less than 10 IU/dL (i.e., less than 10% of normal). A recent study observed measurable VWFpp (median = 72 IU/dL) in a subset of type 3 VWD patients despite very low VWF:Ag levels, indicating that in those cases, VWF is produced and secreted, but rapidly cleared from the circulation.[91] Therefore, the levels of VWFpp may distinguish between type 3 VWD and severe type 1 VWD patients.

Variants associated with type 3 VWD are found throughout the coding region of *VWF*, including the propeptide. Up to 80% of type 3 VWD patients have two null alleles and produce little or no VWF. Null alleles can result from a variety of variants, with nonsense variants accounting for about one-third. Approximately 20% of alleles carry missense variants and are predominantly located in the D1–D2 (exons 3 to 11) and D4–CK (exons 37 to 52) domains. These variants may impair dimer or multimer formation, resulting in intracellular VWF retention and decreased secretion into plasma. Large deletions, predominantly resulting in frameshift variants affecting one or more exons, contribute to approximately 12% of the type 3 VWD variant spectrum. Because there is little or no circulating VWF, patients with these variants may develop alloantibodies against infused VWF.[92]

Low von Willebrand Factor

For many years, there has been debate regarding which cut-off level of VWF should be used for the diagnosis of type 1 VWD. Individuals with mild to moderate reductions in plasma VWF levels (30 to 50 IU/dL) may be considered in a distinct category labeled “low VWF levels” instead of type 1 VWD (levels <30 IU/dL). These individuals display variable bleeding phenotypes and often do not have *VWF* gene sequence variations. A recent large cohort study from Ireland showed that low VWF levels can be associated with significant bleeding which is predominantly due to reductions in VWF synthesis and/or secretion.[93] The underlying pathobiology of low VWF levels remains largely undefined, which poses challenges for the diagnosis and management of these individuals. The ASH/ISTH/NHF/WFH updated guidelines for the diagnosis and management of VWD will be especially critical for the diagnosis and management of this group of patients.

Clinical Manifestations

The bleeding history depends on disease severity; type 3 VWD is often diagnosed early in life, whereas mild type 1 VWD may not be diagnosed until adulthood. Individuals with VWD primarily complain of excessive mucocutaneous bleeding, such as spontaneous, recurrent epistaxis, and prolonged bleeding after dental cleaning or extraction. In addition, prolonged or excessive bleeding after surgery or trauma is often reported. Affected females frequently experience heavy menstrual bleeding from the time of menarche and can have prolonged or excessive bleeding after childbirth.[94] Musculoskeletal bleeding is unusual, except in type 2N or type 3 VWD when the FVIII:C level may be below 10 IU/dL. Bleeding assessment tools (BATs) help to standardize and quantify the bleeding history (see Chapter 126). The occurrence, frequency and severity of various bleeding symptoms are assessed, with each symptom evaluated using a common scoring system.[95] A bleeding score is then generated by summing the score of all bleeding symptoms for a given individual. BATs are helpful for making a VWD diagnosis. In addition, high bleeding scores are predictive of the risk of future bleeding (see Chapter 126).[96]

EXAMPLE OF THE PRESENTATION AND IMPACT OF TYPE 1 VON WILLEBRAND DISEASE

J.C., a 26-year-old female, presents with delayed postpartum hemorrhage (PPH) after the delivery of her first child. The pregnancy and delivery were unremarkable. One week postpartum, the patient experienced heavy bleeding, and required a dilation and curettage. At the same time, she was started on tranexamic acid, which was continued for 2 weeks. By approximately 3 weeks postpartum, there was complete cessation of bleeding. A bleeding history was significant for the following: excessive postsurgical bleeding following tonsillectomy and adenoidectomy, which required red blood cell transfusion; excessive bleeding post-dental extractions, requiring consultation with the dentist and repacking; and heavy menstrual bleeding from the time of menarche, which had been well controlled with a combined oral contraceptive pill. There was no family history of VWD. Investigations revealed VWF:Ag 29 IU/dL, VWF:RCo 28 IU/dL, and FVIII:C 60 IU/dL. Multimer gel was unremarkable. A DDAVP challenge demonstrated that the patient was a responder. She became pregnant again 4 years later. At the time of delivery, she was treated with tranexamic acid and a dose of DDAVP after the cord was clamped. Her postpartum course was uncomplicated.

This case illustrates several important points. First, type 1 VWD is a mild to moderate bleeding disorder. Patients often do not have significant symptoms on a regular basis, or symptoms may be masked or ameliorated by concomitant combined oral contraceptive use, which is common in this patient demographic. A careful bleeding history focusing on past hemostatic challenges, and subsequent complications is vital in making the diagnosis. A high index of suspicion is required for unusual bleeding complications, such as delayed PPH. The importance of making the diagnosis is highlighted here. With little burden of prophylactic treatment, bleeding complications can be avoided.

Type 1 VWD accounts for up to 70% of VWD. It typically manifests as mild mucocutaneous bleeding; however, symptoms may be more severe if VWF levels are below 15 IU/dL. Epistaxis and bruising are common symptoms in children. Heavy menstrual bleeding is the most common finding in women of reproductive age.

Type 2 VWD accounts for about 25% of all VWD. The relative frequency of the subtypes is 2A > 2N > 2M > 2B in European populations. Individuals with type 2A, 2B, and 2M VWD usually present with mild to moderate mucocutaneous bleeding, but bleeding episodes can be severe, particularly when VWF:RCo is very low or absent. In many patients with type 2B VWD, thrombocytopenia can develop or worsen with infection, surgery, pregnancy, or treatment with DDAVP. The symptoms of type 2N VWD are similar to those seen in mild hemophilia A (see Chapter 134) because both disorders are associated with reduced levels of FVIII:C.

Type 3 VWD is the rarest subtype and accounts for less than 5% of VWD. Prevalence estimates range from 0.55 to 6 per million, with higher rates seen with consanguineous marriage.[97] Type 3 VWD manifests with severe bleeding, including excessive mucocutaneous bleeding and musculoskeletal bleeding.

Penetrance

In autosomal dominant type 1 VWD, variants resulting in plasma VWF level less than 25 IU/dL are often fully penetrant, whereas those resulting in higher VWF levels are often incompletely penetrant.[78] Variants responsible for autosomal dominant types of VWD (2A, 2B, and 2M) are often fully penetrant. Thus, in contrast with the variably positive family histories in patients with type 1 VWD, those with type 2 VWD usually have a positive family history.

Laboratory Investigations

The laboratory evaluation for VWD involves a battery of qualitative and quantitative measurements of VWF and FVIII that should be interpreted by a physician with experience in this area given the heterogeneity of possible results (Table 133.2).[98]

Screening Tests

The complete blood cell count may show microcytic anemia because of iron deficiency or thrombocytopenia in type 2B VWD. The aPTT is often normal but may be prolonged if the FVIII:C level is reduced below 30 to 40 IU/dL, as can be seen with severe type 1, type 2N, or type 3 VWD. The prothrombin time is normal in VWD. Although some laboratories may also include a skin bleeding time and platelet function analysis (PFA closure time) in their evaluation of an individual with suspected VWD, these tests lack sensitivity in persons with mild bleeding or specificity for VWD.

Confirming a Diagnosis of von Willebrand Disease

The following specific factor assays should be performed even if the screening tests are normal.

Von Willebrand Factor: Antigen

This assay determines the quantity of VWF protein antigen in the plasma and is performed using an enzyme-linked immunosorbent assay (ELISA) or latex immunoassay (LIA). The normal range (which should be determined independently by each laboratory) is approximately 50 to 200 IU/dL.

Von Willebrand Factor Activity

Until recently, the VWF:RCo assay was the gold standard for the measurement of VWF platelet-binding activity. The VWF:RCo activity assay measures the capacity of VWF to agglutinate platelets in response to ristocetin. However, due to the high coefficient of variation within and between laboratories, the VWF:RCo assay is gradually being phased out in favor of the VWF:GPIbM activity assay.[99] This assay demonstrates improved precision and sensitivity compared with the VWF:RCo assay, and is not subject to the ristocetin-associated artifactual reductions in activity for *VWF* sequence variants p.Pro1467Ser and p.Asp1472His. The normal range for these assays is approximately 50 to 200 IU/dL.

Factor VIII: C Level

The functional FVIII assay determines the activity of FVIII in clot-based assays. The normal range is approximately 50 to 150 IU/dL.

Several analytic variables can complicate the diagnosis of VWD. Based on established reference ranges, approximately 2.5% of the normal population will have low VWF levels. In addition, assay variability, particularly for VWF:RCo, renders differentiation of type 1 VWD from type 2 VWD difficult.

VWF:RCo and VWF:Ag determined by LIA have limited sensitivity, which may result in the misdiagnosis of type 3 VWD as type 1 or type 2 VWD. Finally, inappropriate sample handling can lead to decreases in VWF:Ag, VWF:RCo, and FVIII:C, with VWF:RCo predominantly affected. All these factors must be considered when

TABLE 133.2 **Table of Investigations**

VWD Type	VWF:RCo IU/dL[a]	VWF:Ag IU/dL[a]	RCo/Ag IU/dL[a]	FVIII:C IU/dL[a]	Multimer Pattern[b]	Other
1	Low	Low	Equivalent	~1.5× VWF:Ag	Normal	
2A	Low	Low	VWF:RCo < VWF:Ag	Low or normal	Abnormal↓ HMWM	
2B	Low	Low	VWF:RCo < VWF:Ag	Low or normal	Abnormal↓ HMWM	↑ RIPA[c] (↓ platelet count)
2M	Low	Low	VWF:RCo < VWF:Ag	Low or normal	Normal	
2N	Normal/low	Normal/low	Equivalent	<30	Normal	↓ VWF:FVIIIB[d]
3	Absent	Absent	NA	<10	Absent	

[a] Relative to the reference range (approximate values); VWF:RCo (50–200 IU/dL); VWF:Ag (50–200 IU/dL); FVIII:C (50–150 IU/dL).

[b] HMWM, High-molecular-weight multimers.

[c] Increased agglutination at low concentrations of ristocetin.

[d] The ability of VWF to bind and protect FVIII is reduced. VWF and FVIII levels can look exactly like those in males with mild hemophilia A or in symptomatic hemophilia A carrier females.*Ag*, Antigen, *FVIII:C*, FVIII level; *NA*, not applicable; *RCo*, ristocetin cofactor; *RIPA*, ristocetin-induced platelet aggregation; *VWD*, von Willebrand disease; *VWF:FVIIIB*, FVIII-binding assay.

FACTORS TO CONSIDER WHEN INTERPRETING VON WILLEBRAND DISEASE TEST RESULTS

	Considerations	Results
Preanalytical	When was the sample collected and processed? Was there a significant delay before samples were run? Were samples frozen in a timely fashion?	VWF:RCo may be decreased resulting in a false-positive diagnosis of type 2 VWD
Analytical	Convention of established references	False-positive diagnosis of VWD in 2.5% of population
	High degree of assay variability for VWF:RCo	False-positive diagnosis of type 2 in a type 1 patient may result in the misdiagnosis of type 3 for type 1 or type 2 VWD
	A high lower limit of detection for certain VWF:Ag and VWF:RCo assays, in particular LIA-based assays	
Patient factors	Drugs (OCP, HRT, or valproic acid)	False negative or positive
	ABO type	False negative
	Pregnancy	Reversible acquired von Willebrand syndrome
	Hypothyroidism	
	Comorbid illness (e.g., valvular heart disease, lymphoma)	

Ag, Antigen; *HRT*, hormone replacement therapy; *LIA*, latex immunoassay; *OCP*, oral contraceptive pill; *RCo*, ristocetin cofactor; *VWD*, von Willebrand disease; *VWF*, von Willebrand factor.

interpreting VWF laboratory results, and at least two sets of tests using fresh samples are needed to confirm the diagnosis of VWD. Diagnostic testing should be avoided in stressed, ill, or pregnant patients (see box on Factors to Consider When Interpreting von Willebrand Disease Test Results).

Discriminating Tests to Identify von Willebrand Disease Subtype

Von Willebrand Factor Multimer Analysis

Sodium dodecyl sulfate (SDS)-agarose electrophoresis is used to assess VWF oligomers in plasma (see Fig. 133.4). Normal plasma contains multimers composed of over 40 VWF subunits. The largest multimers have molecular weights more than 20,000 kDa. Multimers are classified as HMW, IMW, and LMW by counting bands 1 to 5 as LMW, 6 to 10 as IMW, and those above 10 as HMW.[100] HMW and/or IMW multimers are decreased or missing in types 2 A and 2B VWD. Infrequently, circulating UL-VWF multimers may be apparent in the plasma. These are associated with pathological conditions such as thrombotic thrombocytopenic purpura and have also been observed in VWD Vicenza.

Low-Dose Ristocetin-Induced Platelet Aggregation

The RIPA assay tests the capacity of VWF to agglutinate platelets with varying concentrations of ristocetin. In contrast to the VWF:RCo (which evaluates the interaction between the patient's VWF and formalin-fixed platelets), the low-dose RIPA assay evaluates the sensitivity of the patient's platelets to low-dose ristocetin. In cases of type 2B or platelet-type VWD (PT-VWD), the platelet membrane is "overloaded" with high-affinity mutant VWF, resulting in abnormal platelet agglutination with low ristocetin concentrations. In some cases of type 2B VWD, all variables except low-dose RIPA may be normal. RIPA at normal ristocetin concentrations should be normal in type 1 VWD unless VWF levels are below 10 to 20 IU/dL.

Binding of Factor VIII by von Willebrand Factor

The VWF:FVIIIB ELISA determines the ability of VWF to bind FVIII and is useful for the diagnosis of type 2 N VWD. There are no standard units for the output of this test.

Collagen Binding Assay

The VWF:CB ELISA determines the ability of VWF to bind collagen and is dependent on HMW VWF multimers. Consequently, the test helps to identify functional VWF discordance (i.e., to distinguish between types 1 and 2 VWD).[101] Reduced collagen binding reflects the loss of HMW multimers, or can reflect a specific collagen-binding deficiency (type 2 M VWD). The normal range is approximately 50 to 200 IU/dL.

Von Willebrand Factor Propeptide/Antigen Ratio

An increased ratio of steady-state plasma VWFpp to VWF:Ag identifies patients with variants that cause accelerated VWF clearance.[65] A ratio >2.2 is considered indicative of an accelerated VWF clearance phenotype.

Desmopressin Responsiveness

DDAVP administration releases VWF stores from endothelial cells. The pattern of DDAVP response in VWD subtypes (Table 133.3) may help to assign VWD subtype. In addition, a decrease in the duration of the DDAVP response may indicate increased VWF clearance.

Genotyping

The identification of a variant is not necessary for the diagnosis of VWD. However, genotyping should be considered when specialized testing with the VWF:FVIIIB assay is unavailable and type 2 N VWD is suspected. Genotyping is also useful to discriminate between type 2B VWD and PT-VWD, and for prenatal assessment and alloantibody risk assessment in type 3 VWD. In mild-type 1 VWD, the likelihood of finding a pathological variant is low because variants are not localized to a particular domain or exon and the results are of little clinical utility.

Differential Diagnosis

Hemophilia A

Both type 2 N VWD and mild hemophilia A (caused by variants in *F8*) result in reduced levels of FVIII:C (approximately 5 to 40 IU/dL) with normal or borderline low levels of VWF. Although the VWF:FVIIIB test distinguishes between the two disorders, the test is not widely available and the results may be equivocal.

In families with reduced FVIII:C, an X-linked pattern of inheritance helps identify those with mild hemophilia A. When family history is uninformative and VWF levels and function are normal, it may be preferable to perform sequence analysis of the *F8* gene before the *VWF* gene, even in symptomatic females who are simplex cases (i.e., a single occurrence in a family), because *F8* variant and skewed X-chromosome inactivation (lyonization) are often responsible for symptoms. *F8* variants may be detected in more than 50% of cases referred for "possible 2 N VWD or hemophilia A." When *F8* variants are absent, or if the VWF level and function are also abnormal, *VWF* can be analyzed.

Platelet-Type von Willebrand Disease

PT-VWD, also called *pseudo VWD*, mimics type 2B VWD but is caused by variation in platelet *GPIBA*. The disorders can be distinguished by mixing patient platelets or plasma with control plasma or platelets and using aggregometry or flow cytometry to identify the defective component.[103] However, these assays are technically challenging. In the absence of variants in exon 28 of *VWF*, variants in exon 2 of *GPIBA* are identified in approximately 10% of persons misdiagnosed with type 2B VWD. To date, a number of missense variants have been identified including those more commonly affecting GPIbα AA p.Gly249 and p.Met255, as well as a 27 bp in-frame deletion c.1345_1371del27 (p.Pro449_Ser457del). Misdiagnosis of PT-VWD may result in ineffective treatment of patients. VWF concentrate is needed to correct the reduced VWF level, but platelet transfusion may also be required if there is significant thrombocytopenia. The half-life of replaced VWF is reduced in PT-VWD because of binding to abnormal GPIbα. Consequently, VWF concentrate must be administered more frequently.

Acquired von Willebrand Syndrome

This mild to moderate bleeding disorder is a result of an acquired deficiency or dysfunction of VWF. Exclusion of a lifelong personal and family history of bleeding is an important aspect of the diagnosis. Although acquired von Willebrand syndrome (AVWS) was thought to be uncommon, cohort studies suggest that the prevalence may be significantly underestimated.[104] When selected patient populations were screened, approximately 10% of patients with hematologic disorders, approximately 79% with aortic stenosis, and up to 100% with left ventricular assist devices were diagnosed with AVWS. The median age of diagnosis is 62 years, but the disorder may occur in any age group (range 2 to 96 years). AVWS has diverse pathology and may result from autoantibodies that impair VWF function or increase its clearance, adsorption of HMW VWF multimers to malignant cells or platelets, proteolytic cleavage of VWF after shear stress-induced unfolding, or decreased VWF synthesis. Diseases that have been implicated include (1) lymphoproliferative disorders and plasma cell dyscrasias, including monoclonal gammopathy of unknown significance, multiple myeloma, and Waldenström macroglobulinemia; (2) autoimmune disorders, including systemic lupus erythematosus, scleroderma, and antiphospholipid antibody syndrome; (3) aortic stenosis and ventricular septal defects, which can trigger shear-induced conformational changes that increase VWF proteolysis; (4) thrombocytosis, including myeloproliferative neoplasms that lead to a type 2 phenotype; (5) Wilms tumor or lymphoproliferative disorders that can be associated with increased VWF clearance by aberrant binding to tumor cells; (6) decreased VWF synthesis, for instance, with hypothyroidism, and drugs including valproic acid, ciprofloxacin, griseofulvin, and hydroxyethyl starch. The treatment goals can be divided into two categories: (1) treatment or prevention of bleeding and (2) induction of long-term remission.[105] The agents used for prevention and treatment of bleeding in AVWS overlap with those used in VWD and include DDAVP or VWF-containing concentrates, which can transiently increase VWF levels. Other options include recombinant factor VIIa (rFVIIa), antifibrinolytic agents, intravenous immunoglobulin, or plasmapheresis for AVWS associated with monoclonal gammopathies. Often a combination of agents is required to affect hemostasis. Maneuvers to induce long-term remission will depend on the underlying pathogenic etiology of AVWS. Whenever possible, treatment of the underlying disorder should be considered and may result in remission of the AVWS.

Management of von Willebrand Disease

The approach to the management of VWD is summarized in Fig. 133.6.

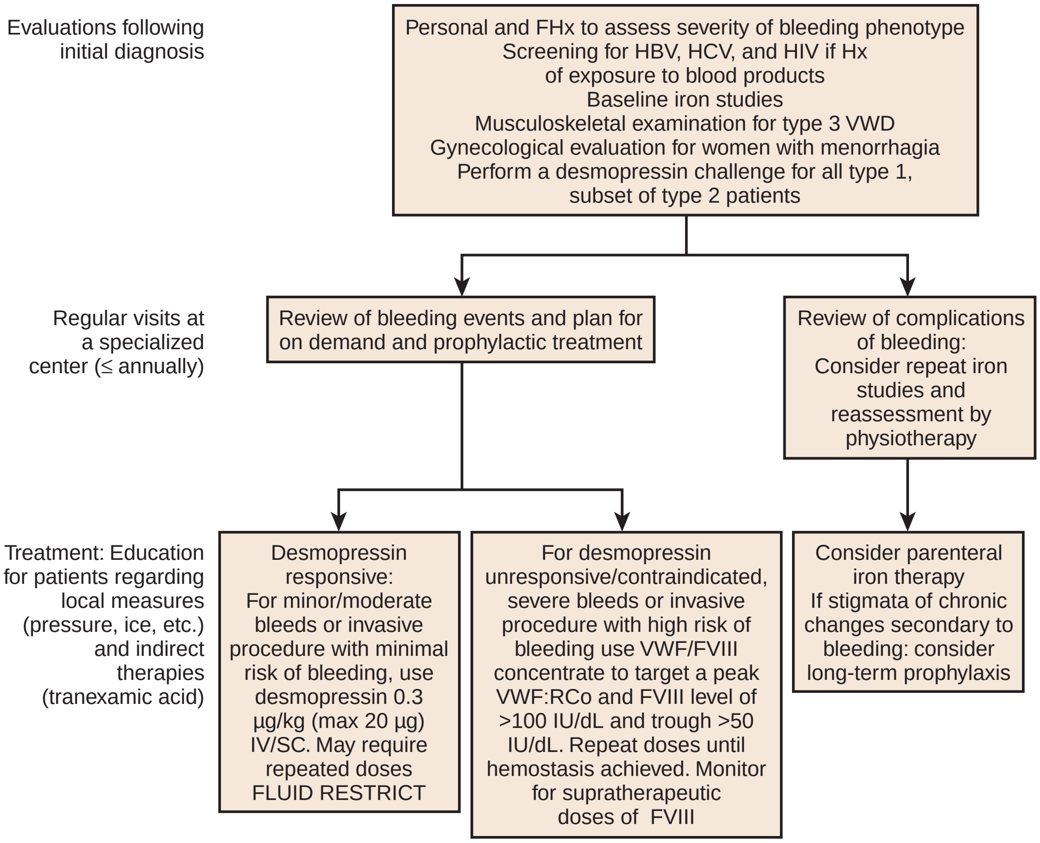
Evaluations Following Initial Diagnosis

To establish the extent of disease in an individual diagnosed with VWD, the following evaluations are recommended: (1) a personal and family history of bleeding to help predict severity and tailor treatment (use of a standardized BAT can be helpful); (2) a joint and muscle evaluation for those with type 3 VWD (musculoskeletal bleeding is rare in types 1 and 2 VWD); (3) screening for hepatitis B and C, as well as HIV if the diagnosis is type 3 VWD, or if the individual received blood products or plasma-derived clotting factor concentrates before 1985 (this screening should be followed by vaccinations for hepatitis A and B); (4) determination of serum iron and ferritin (to assess iron stores), because many individuals with VWD are iron deficient, particularly women with heavy menstrual bleeding; and (5) gynecologic evaluation for women with heavy menstrual bleeding. Individuals with VWD benefit from referral to a comprehensive bleeding disorders program for education, treatment, and genetic counseling.

TABLE 133.3 **Desmopressin Responsiveness in the Various Subtypes of von Willebrand Disease**

VWD Type	VWF:RCo	VWF:Ag	RCo/Ag	FVIII:C	VWF:CB	VWF:CB/VWF:Ag
1	Increase	Increase	Remains >0.7	Increase	Increase	Remains >0.7
2 A	No/little change	Increase	Remains <0.7	Increase	No/little change	Remains <0.7
2 M (GPIB binding dysfunction)	No/little change	Increase	Remains <0.7	Increase	Increase	Remains >0.7
3	No/little change	No/little change		No/little change	No/little change	

Ag, Antigen; *CB*, collagen binding assays; *FVIII:C*, factor VIII level; *GPIB*, glycoprotein 1B; *RCo*, ristocetin cofactor; *VWD*, von Willebrand disease; *VWF*, von Willebrand factor.
Modified from Favaloro EJ. Rethinking the diagnosis of von Willebrand disease. *Thromb Res.* 2011;127 Suppl:S17–21.[102]



Evaluations following initial diagnosis
Personal and FHx to assess severity of bleeding phenotype
Screening for HBV, HCV, and HIV if Hx of exposure to blood products
Baseline iron studies
Musculoskeletal examination for type 3 VWD
Gynecological evaluation for women with menorrhagia
Perform a desmopressin challenge for all type 1, subset of type 2 patients
Regular visits at a specialized center (≤ annually)
Review of bleeding events and plan for on demand and prophylactic treatment
Review of complications of bleeding: Consider repeat iron studies and reassessment by physiotherapy
Treatment: Education for patients regarding local measures (pressure, ice, etc.) and indirect therapies (tranexamic acid)
Desmopressin responsive: For minor/moderate bleeds or invasive procedure with minimal risk of bleeding, use desmopressin 0.3 µg/kg (max 20 µg) IV/SC. May require repeated doses FLUID RESTRICT
For desmopressin unresponsive/contraindicated, severe bleeds or invasive procedure with high risk of bleeding use VWF/FVIII concentrate to target a peak VWF:RCo and FVIII level of >100 IU/dL and trough >50 IU/dL. Repeat doses until hemostasis achieved. Monitor for supratherapeutic doses of FVIII
Consider parenteral iron therapy
If stigmata of chronic changes secondary to bleeding: consider long-term prophylaxis

Figure 133.6 APPROACH TO THE MANAGEMENT OF VON WILLEBRAND DISEASE (VWD). *FHx*, Family history; *FVIII*, factor VIII; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *Hx*, history; *IV*, intravenous; *RCo*, ristocetin cofactor; *SC*, subcutaneous; *VWF*, von Willebrand factor.

Treatment of von Willebrand Disease

The management of VWD can be divided into three main categories: (1) localized measures to stop or minimize bleeding; (2) pharmacologic agents that provide indirect hemostatic benefit; and (3) treatments that directly increase plasma VWF and FVIII levels.[98]

Localized Measures

The importance of localized measures to control bleeding in VWD, such as the application of direct pressure to a site of bleeding or injury, should not be understated. Biting down on a piece of gauze may halt bleeding from a tooth socket, and application of a compression bandage and cold pack to an injured limb may reduce subsequent hematoma formation. With epistaxis, patients may benefit from a stepwise action plan that escalates from pressure to packing after a certain time period. In selected cases, nasal cautery may be required for prolonged or excessive epistaxis.

Several topical hemostatic agents that are predominately used to achieve surgical hemostasis may have a limited role in the treatment of VWD and bleeding; these include gelatin foam/matrix, topical thrombin, and fibrin sealants.

Indirect Therapies

Fibrinolytic inhibitors (e.g., tranexamic acid), which inhibit the conversion of plasminogen to plasmin, can be used either as sole therapy, or as adjuncts to DDAVP or VWF/FVIII concentrates, and may be particularly useful to control mucosal bleeding in the oral cavity or gastrointestinal (GI) or genitourinary tracts.[98] The most common adverse events to tranexamic acid are GI side-effects and headache. Tranexamic acid is contraindicated in disseminated intravascular coagulation and bleeding from the upper urinary tract, where it can lead to obstruction by clots. Hormonal treatments (i.e., the combined oral contraceptive pill) are effective for the treatment of menorrhagia. Nonmedical treatments, such as levonorgestrel-releasing intrauterine systems or endometrial ablation, may be useful in select patients with VWD.

Desmopressin

Most individuals with type 1 VWD and some with type 2 VWD respond to intranasal, intravenous, or subcutaneous treatment with DDAVP, which promotes release of stored VWF and raises levels 3- to 10-fold.[18] Peak effects are achieved 30 and 90 minutes after intravenous and intranasal delivery, respectively. The usual parenteral dose is 0.3 µg/kg infused intravenously in approximately 50 mL of normal saline over approximately 30 minutes. The dose of the highly concentrated intranasal preparation is 150 µg for children under 50 kg and 300 µg for larger children and adults. It is important to note that highly concentrated products (e.g., Stimate) deliver 150 µg per spray, a much higher concentration than that used to treat enuresis.

After VWD diagnosis, a DDAVP challenge is advisable to assess VWF response. VWF and FVIII levels should be determined before, and at several points, after DDAVP administration (e.g., at baseline and at 1- and 4-hours post-administration). A three-fold increase in VWF and FVIII levels to at least 30 IU/dL (30%) is usually considered adequate for situations such as dental procedures, minor surgery, or the treatment of epistaxis or menorrhagia.

DDAVP is safe and generally well tolerated. Common side effects include facial flushing and headache. Tachycardia, lightheadedness, and mild hypotension can occur. The most serious side effects are severe hyponatremia and seizures. Reduction of fluid intake for 24 hours after DDAVP administration is an important precaution to prevent water intoxication. Serum sodium levels should be monitored in patients receiving repeated doses of DDAVP. In addition, DDAVP should be used with caution in those younger than 2 years of age because of a higher risk for hyponatremia.[98] There are case reports of DDAVP precipitating coronary artery vasospasm and acute myocardial infarction.[106,107] Therefore, DDAVP should be used with caution in patients with a history of coronary artery disease or in the older adult. In persons who are intolerant to DDAVP or have a poor VWF response, clotting factor concentrate is required.

An important limitation in the use of DDAVP is the development of tachyphylaxis with repeated administration. When given repeatedly at intervals of less than 24 hours, the magnitude of the VWF and FVIII increments can fall to approximately 70% of those obtained with the initial dose. For practical purposes, a single dose of DDAVP before dental extractions or minor procedures is usually sufficient. Although repeated doses can be given at 12 or 24 hours, the potential for tachyphylaxis must be considered. Additionally, in situations where repeat dosing is considered, more prolonged fluid restriction is required.

Although most type 1 VWD patients respond adequately to DDAVP, type 3 VWD patients typically do not respond to this drug, and the response in type 2 VWD patients is variable.[108] Type 2 A patients often exhibit an adequate response and may benefit from a DDAVP trial. Type 2 M patients typically do not respond well to DDAVP. DDAVP is generally contraindicated in type 2B VWD because of the transient thrombocytopenia that accompanies the release of mutant VWF. In type 2 N VWD, DDAVP produces a two- to ninefold increase in FVIII, but the increase persists for approximately 3 hours. Therefore, DDAVP should be reserved for situations in which a transient rise in FVIII is sufficient.

Von Willebrand Factor/Factor VIII Concentrates

VWF/FVIII concentrates are required for patients who do not have an adequate response, experience significant side effects, or have contraindications to DDAVP. Because of tachyphylaxis and the risk of hyponatremia with DDAVP, patients with severe bleeding or those requiring major or repeated surgery often need VWF replacement therapy. Purified, viral-inactivated, plasma-derived VWF/FVIII is the product most frequently used (e.g., Humate-P, Wilate). The quantity of ristocetin cofactor activity (VWF:RCo) relative to FVIII:C varies by product; Humate-P contains 2.4 VWF:RCo units for each 1 FVIII:C unit, whereas Wilate contains a 1:1 ratio. Both products contain a full spectrum of VWF multimers, including HMW multimers, and closely resemble normal plasma. Highly purified FVIII concentrates (monoclonal antibody purified and recombinant) should not be used to treat VWD because they lack VWF.

Dosing recommendations are provided either in VWF:RCo (North America) or FVIII:C (Europe) units and are weight-based; repeat infusions can be given every 8 to 24 hours, depending on the clinical situation. The goal is to maintain VWF:RCo and FVIII:C at more than 100 IU/dL at peak and at more than 50 IU/dL at trough until hemostasis is achieved. With VWF/FVIII concentrates, the FVIII:C response is higher and more sustained than predicted from the dose because of the stabilizing effect of exogenous VWF on endogenous FVIII. Details regarding dosing can be found in the product inserts. VWF:RCo and FVIII:C levels should be measured in patients receiving repeat infusions, not only to ensure adequate hemostasis, but also to monitor for supraphysiological levels of FVIII because thromboembolic events have been associated with high FVIII levels. The overall incidence of thrombotic events is low, and most cases occur in surgical patients with other risk factors. Therefore, mechanical and anticoagulant thromboprophylaxis should be considered on a case-by-case basis. Adverse reactions to VWF/FVIII concentrates are rare but include allergic and anaphylactic symptoms, such as urticaria, chest tightness, rash, pruritus, and edema.

VWF/FVIII concentrates are effective in over 97% of events.[109] In the rare event that infusion of a VWF/FVIII concentrate is ineffective at stopping bleeding transfusion of platelet concentrates may be beneficial, presumably because they facilitate the delivery of small amounts of platelet VWF to the site of vascular injury.
